FOREWORD

This data dump describes the experimental work and the data collected during Phase I of the "Photographic Combustion Characterization of LOX/HC Type Propellants" Program. The activity was performed by Aerojet Liquid Rocket Company on contract NAS 9-15724, under the direction of Mr. M. F. Lauster, NASA-JSC Project Manager. Aerojet personnel included Mr. J. W. Salmon, Program Manager; Mr. B. R. Lawver, Project Manager, and Mr. D. C. Judd, Project Engineer. The following individuals also contributed to the program:

Gene Hron	Fabrication
Arnold Keller	Test Engineering
Lee Lang	Injector Design

I. INTRODUCTION AND SUMMARY

A. INTRODUCTION

The objectives of this program are two-fold. The first objective (Phase I) is to experimentally demonstrate the advantages and limitations of using high speed photography to identify and characterize potential anomalies (i.e., pops, fuel freezing, thermal decomposition, and reactive stream separation) in the combustion of liquid oxygen (LOX)/Hydrocarbon (HC) type propellants while operating with different element concepts. The second objective (Phase II) is to develop a combustion evaluation criteria based on the above mentioned testing and use it to evaluate, characterize, and screen promising low cost LOX/HC type propellants for long life reusable propulsion systems. The basic injector element combustion data generated in this effort will provide much of the needed experimental data necessary to rationally select the most promising propellant combination(s) and injector elements for future engine technology efforts and engine development programs. Without this experimental data, compromises will have to be made between risk and the present state-of-the-art data base. This could result in either significant development cost and/or operational costs being incurred unnecessarily.

B. SUMMARY

The development work undertaken during Phase I resulted in the design and testing of three single element injectors and two fuels with the aim of photographically characterizing observed combustion phenomena. The three injectors tested were the O-F-O triplet, the Transverse Like on Like (TLOL), and the Rectangular Unlike Doublet (RUD). The fuels tested were RP-1 and Propane.

The hot firings were conducted in a specifically constructed chamber fitted with quartz windows for photographically viewing the impingement spray field.

I, B, Summary (cont.)

Test results from Phase I main chamber element testing show that the appearance of LO₂/hydrocarbon combustion is markedly different from storable propellant combustion observed on previous blowpart tests (Contract NAS 9-14186, Ref. 1). However, the pressure effects on combustion show similar trends. All LOX/HC testing demonstrated coking with the RP-1 fuel leaving far more soot than the Propane fuel. No fuel freezing or popping was experienced under the test conditions evaluated during Phase I. Carbon particle emission and combustion lightbrilliance increased with Pc for both fuels although RP-1 was far more energetic in this respect. RSS phenomena appear to be present in the high Pc tests as evidenced by striations in the spray pattern and by separate fuel rich and oxidizer rich areas.

The RUD element was also tested as a fuel rich gas generator element by switching the propellant circuits. Excessive sooting occurred at this low mixture ratio (0.55), precluding photographic data.

Testing to date has increased our knowledge of LOX/HC combustion phenomena and has shown that some of the anticipated problems (i.e., fuel freezing, flash vaporization, etc.) are not likely to occur at the test conditions being examined. Further testing with new elements and fuels will be necessary to characterize the above mentioned combustion phenomena more precisely. This testing will be performed during Phase II of this program.

II. RESULTS AND CONCLUSIONS

A. RESULTS

A summary of the most important findings from Phase I testing is shown below:

Fuel Freezing or Pops - No occurrence of fuel freezing or popping was noted with the use of LOX/RP-1 in three Phase I injectors (OFO triplet, TLOL, and RUD). Although this is a significant finding, it is not conclusive evidence that freezing and popping will not occur with other injectors and propellants (e.g., LOX/NH₃). The use of larger orifices than those in this program (.030 in.) may also promote fuel freezing. Larger streams would receive proportionally less heat from recirculation gases because of their reduced surface area to volume ratio.

Coking - Coking was influenced by type of fuel, mixture ratio, and injector element. RP-1 definitely deposited more soot than Propane for a given injector. Lower mixture ratios resulted in coking which coated the chamber and windows precluding photography. The RUD with its coherent jet impingement resulted in greater soot formation than the TLOL with its spray fan impingement. The TLOL appeared to atomize, mix, and burn more completely.

Reactive Stream Separation (RSS) - There appears to be an RSS type of phenomena as evidenced by striations in the spray pattern and by separate areas of fuel and oxidizer rich propellants. There does seem to be a Pc dependence with better mixing and less combustion light emission at the lower pressures. Higher pressure seems to promote the apparent separation and greatly enhance the light emission. Light intensity increases during RSS because of the carbon formation resulting from poor mixing and incomplete combustion. Verification of RSS and correlations between RSS and velocity, mixture ratio, orifice diameter, injector type, or propellants will be a major goal of Phase II of this program.

II, A, Results (cont.)

Super Critical Pressure Operation - No occurrence of flash vaporization leading to resurge phenomena has been experienced at sub-critical or super-critical pressure operation. As mentioned previously there is an increase of light emission and apparent separation with an increase in P_c . This increase, however, is gradual and continuous and seems to bear no relationship to the critical pressure.

Fuel Type - RP-1 produces a brilliant combustion flame which is surrounded by turbulent, dark, recirculation gas flows. The fuel fan (TLOL) is black as it exits the injector and the oxidizer fan is a light gray color. Combustion light increases with chamber pressure and coking is always present.

Propane has a lower rate of carbon particle emission and therefore produces a much less brilliant combustion flame. The fuel fan is a grayish-brown color as it exits the injector and the oxidizer fan is a light gray color. Combustion light also increases with chamber pressure, but to a lesser degree than with LOX/RP-1. A brownish vapor is visible in the low pressure tests, resulting from Propane's high vapor pressure. Propane demonstrates far less carbon deposition or sooting than RP-1.

Main Chamber vs Gas Chamber - All of the above findings are in reference to main chamber operating conditions. The RUD injector element was fired with LOX/C₃H₈ at $P_c = 850$ psia and $MR = .55$ to examine fuel rich gas generator effects. The injector burned smoothly but yielded no photographic data because of excessive sooting. The windows and chamber are completely covered with soot and allowed no penetration of light.

B. ADVANTAGES AND LIMITATIONS OF USING HIGH SPEED PHOTOGRAPHY TO CHARACTERIZE ANOMALIES ON LOX/HC COMBUSTION

1. Advantages

Phase I high speed photography of single element, LOX/HC

II, B, Advantages and Limitations of Using High Speed Photography to Characterize Anomalies in LOX/HC Combustion (cont.)

injectors has been effective in showing the existence of coking and an apparent RSS phenomena and in demonstrating the absence of fuel freezing, as described in the previous section. Each injector/fuel combination tested to date has yielded different results as discussed in Section II,A. Physical processes such as fuel decomposition, mixing, atomization, vaporization, and apparent separation are visible in varying degrees of clarity in each test. Being able to see and interpret these occurrences has resulted in a better general understanding of the LOX/HC combustion process.

2. Limitations

In Phase I testing, emphasis was directed toward obtaining information about a concept or method that could be used to provide data necessary to screen and evaluate various fuels and injector elements. The advantages listed above are important, but for the most part are qualitative. Certain physical processes have been seen to occur as expected (such as coking, extreme brightness, an apparent RSS type of phenomena), but the ability to develop empirical correlations between test conditions and combustion phenomena is still in question. Although testing has been limited to date (44 tests, three injectors, and two fuels), the LOX/HC photographic results are more vague and difficult to obtain than the photos from the N_2O_4 /Amine program. Testing to date indicates that some injector/fuel combinations will never give good photographic results regardless of the technique used (e.g., the RUD fuel rich gas generator). It is believed that the photographic technique now in use is the most flexible and efficient to be utilized, but is compromised by soot and fog formation under many design and operating conditions. Testing with Methane and Ammonia in Phase II may alleviate these sooting and clouding problems somewhat and aid in developing empirical correlations for these two fuels. The possibility of adding a dye to Propane to aid in film interpretation may also facilitate a greater understanding of the combustion process. For this reason it is felt that Phase II photography is worth pursuing using the methods developed during Phase I.

II, B, Advantages and Limitations of Using High Speed Photography to Characterize Anomalies in LOX/HIC Combustion (cont.)

The question naturally arises as to whether photographic observations alone will suffice or whether other methods of confirming the existence of RSS and other phenomena should be employed. The use of larger, multiple element injectors would allow the accurate measurement of Isp and C* which would in turn reflect the occurrence of RSS. It is felt that multiple element testing will be a necessary part of the injector and fuel evaluation and will serve to answer questions perhaps not addressed by single element photographic testing.

C. CONCLUSIONS

The most significant conclusions drawn from the work in Phase I are:

1. RSS appears to occur with non-hypergolic fuels (RP-1 and Propane), and shows a tendency to increase with chamber pressure.
2. Fuel freezing and popping is not observed with the injector elements and operating conditions tested to date (.030 in. jets with RP-1 and Propane).
3. Operation at supercritical pressure is not noticeably different than operation at subcritical pressure, even though the LOX is observed to vaporize more rapidly as chamber pressure is increased.
4. Thermal decomposition and sooting increase as the hydrogen-to-carbon ratio decreases. The type of injector element also influences coking with the coherent jet unlike doublet depositing far more soot than the TLOL or OFO.
5. Photographic characterization of a fuel rich gas generator will be very difficult because of the excessive sooting.

III. RECOMMENDATIONS

A recommendation (along with all supporting rationale) as to the propellants, elements, and operating conditions to be considered in Phase II was prepared and submitted to NASA-JSC for review and approval (Ref. 2). A summary of these recommendations is shown below:

1. Further testing of six elements (four main chamber and two gas generator), and three fuels (Propane, Methane, and Ammonia) are recommended to aid in characterizing LOX/HC combustion phenomena.
2. Efforts should be made to develop empirical correlations between test conditions and LOX/HC combustion phenomena so that future LOX/HC engines can be designed more efficiently.

IV. TECHNICAL DISCUSSION

A. EXPERIMENTAL HARDWARE AND TEST SETUP

1. Test Apparatus

The test apparatus consists of a test chamber equipped with transparent viewing ports, a LOX/H₂ igniter, removable injectors, and nozzles as shown in Figure 1. The test chamber was designed during the Task III "Blowpart" program (Ref. 1) and was modified slightly for use during this program. Of the three injectors fired during Phase I, one of them (O-F-O triplet) was residual hardware from the "Storables Blowpart" program (Contract NAS 9-14186) and two of them (Transverse Like on Like and Rectangular Unlike Doublet) were designed and fabricated during Phase I.

a. Test Chamber

The test chamber was machined from a 4-inch square x 6-inch long block of 304 CRES. The combustion chamber section is 4 inches (10.16 cm) long, to which a 2 in. (5.08 cm) L* spacer is bolted to increase the combustion zone length to 6 inches (15.2 cm). The block was bored to provide a 2.75 inch (6.99 cm) diameter combustion chamber. Four circular quartz windows were provided to facilitate photography and to allow flexibility in photographic lighting of the combustion process. The windows are 1/2 inch (1.27 cm) thick to provide a safety margin for 1000 psia ($6.89 \times 10^5 \text{ N/m}^2$) operation. The flat quartz windows are sandwiched between durabula gaskets for cushioning against ignition shocks and uneven loading. A silicon "O" ring provides sealing on the window periphery. Quartz windows are used to provide good propellant compatibility and well defined optical properties. Thin quartz disc inserts are also employed to protect the 1/2" pressure bearing windows from high heat flux and window damage.

Figure 1. Test Chamber Assembly

IV, A, Experimental Hardware and Test Setup (cont.)

The chamber was designed to provide an inert gas (GN₂) film purge to prevent obscuring the view of propellant spray impingement on the windows. The gas purge flow is injected through four inlets into an annular manifold. The gas is directed from the manifold through an annular gap and made to flow around the periphery of the chamber wall. The gas passages were sized such that the GN₂ is injected into the chamber at 50 ft/sec (15.2 m/sec) at 300 psia (2.07×10^6 N/m²) chamber pressure to minimize mixing with the propellant spray and combustion gas. Storable propellant "Blowpart" testing (Ref. 1) showed that the cold GN₂ purge gas causes poor spray field visibility due to the density gradient created between it and the hot combustion gas. Therefore all subsequent storable propellant tests were run without purging during hotfire. However, it was necessary to re-activate the purge circuit for LOX/HC testing. A helium, in place of GN₂, purge is used to protect the windows from the LOX spray during the start transient and from carbon deposits during shutdown. It automatically shuts off during steady state operation.

Provisions were made for mounting both high and low frequency response pressure transducers and thermocouples. The nozzles consist of removable copper inserts drilled to provide the desired operating pressures. The nozzle configuration and exiting sizes are shown in Figure 2.

b. Igniter

The igniter shown in Figure 3 operates on gaseous hydrogen and oxygen which are ignited by a spark plug. This assembly is an existing igniter that has been used on many high pressure programs proving extremely reliable. The igniter is mounted in a port drilled into the L* spacer section by means of an adapter (see Figure 4). The igniter operates at a mixture ratio of 2.0 and a chamber pressure of 250 psia during hotfire testing.

IV, A, Experimental Hardware and Test Setup (cont.)

c. Injectors

Three injectors; the OFO Triplet, Transverse Like-on-Like (TLOL) and Rectangular Unlike Doublet (RUD) were tested during Phase I. All of the injectors were made in a cylindrical "piston" shape to fit into the chamber purge ring located at the forward end of the chamber. The injector is held in the purge ring by allen head screws. A silicon rubber O-ring seals the injector to the purge ring.

(1) O-F-O Triplet

The OFO triplet shown in Figure 5 is residual hardware from Contract NAS 9-14186. It was designed for testing with LOX/Propane propellants but was not tested at that time due to a program redirection.

The OFO arrangement was selected to maximize the oxidizer to fuel interface to maximize the potential for fuel freezing. The fuel is injected axially and the oxidizer is fed from the inlet tube to a torus which feeds two orifices 180° apart. The impingement half angle is 30°. The .030 in. diameter orifices are EDM'd in the torus cover which is EB welded to the body.

(2) TLOL

The TLOL (Figure 6) is a photoetched platelet injector which was selected for the following reasons:

(a) Like impingement and self-atomizing injectors are predicted to inhibit fuel freezing.

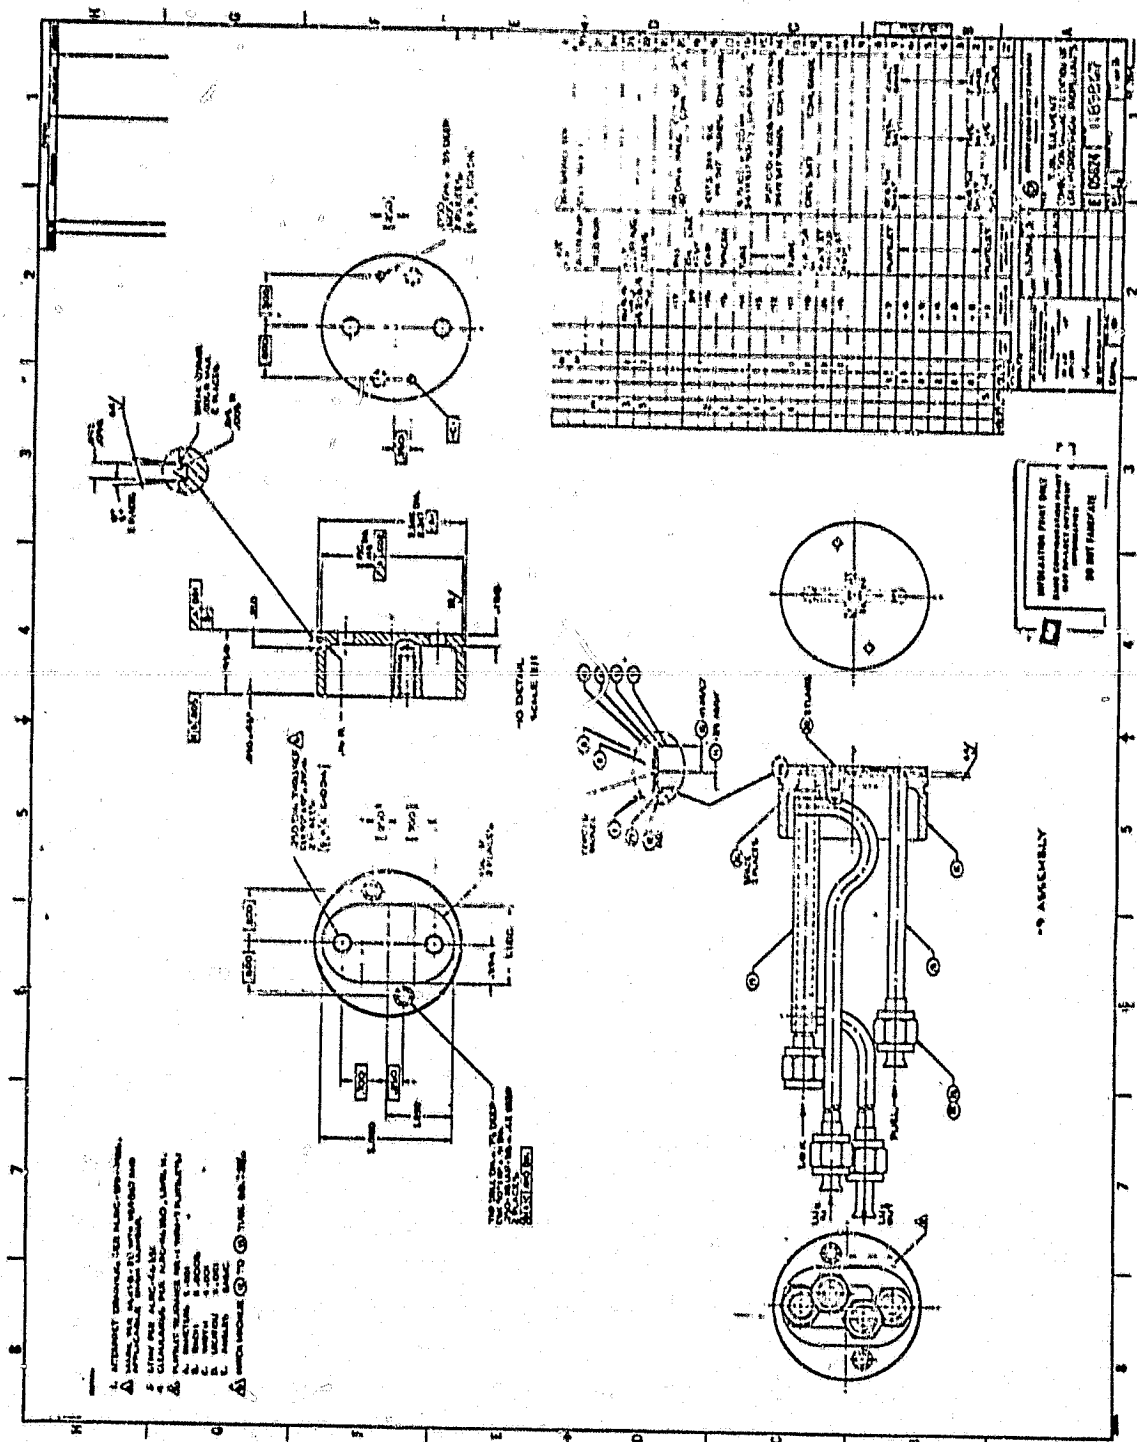

Figure 6. TL0L Element Injector (Sheet 1 of 3)

Figure 6. TL0L Element Injector (Sheet 2 of 3)

Figure 6. ILOL Element Injector (Sheet 3 of 3)

IV, A, Experimental Hardware and Test Setup (cont.)

(b) Self-atomizing injectors promote RSS.

(c) Like impinging doublets can be operated over a wide range of MR, P_c , and T_f with little effect on resultant spray angle.

(d) This element is well characterized and is predicted to produce acceptable combustion stability and performance characteristics.

The single element TLOL was designed for the following nominal operating conditions: (1) $F = 50 \text{ lbf}$, (2) $MR = 2.8$ with RP-1 and $MR = 3.0$ with propane, (3) $P_c = 1000 \text{ psia}$, (4) $\Delta P_{ox} = \Delta P_f = 250 \text{ psi}$.

The TLOL consists of a body, inlet lines, a manifold platelet stack, and an element platelet stack. The manifold stack shown in Figure 7 provides propellant routing and thermal isolation. The element stack (Figure 8) contains the transverse inertance channel to the injection orifice. The platelet stacks are diffusion bonded and then brazed to the body.

(3) RUD

The RUD (Figures 9 through 11) is an EM'd injector fed directly from inlet tubes. The injector face is machined so that the propellants are injected in streams normal to the face. A rectangular orifice configuration was selected to avoid the large diameter mismatch associated with LOX/HC circular orifices. The circular orifice diameter mismatch produces a "banana" shaped spray distribution which is difficult to interpret photographically. The RUD is complimentary to the TLOL for the following reasons:

Figure 7. TL0L Manifold Stack

Figure 8. TL0L Element Stack

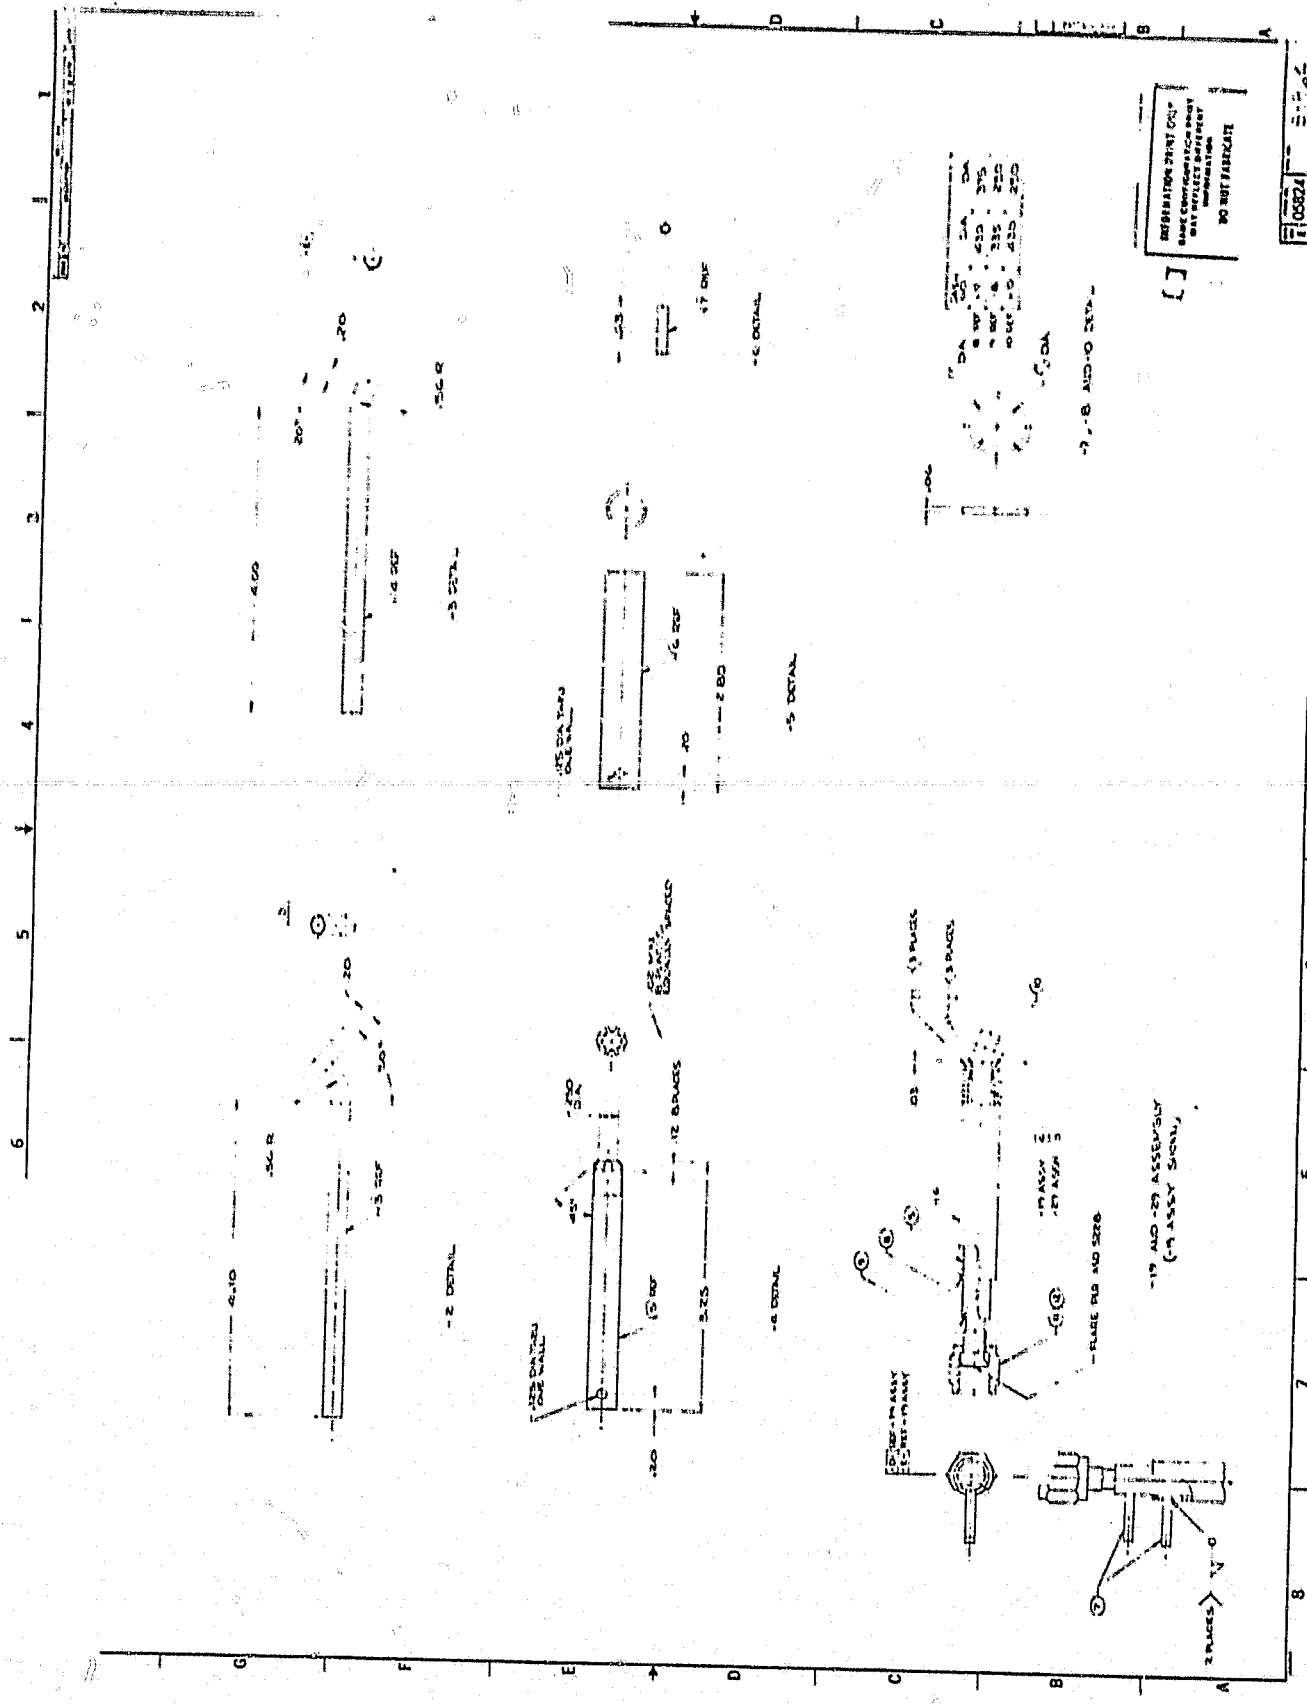

Figure 9. Rectangular Unlike Doublet Combustion Characterization of LOX/HC Propellants (Sheet 2 of 2)

Figure 10. Rectangular Unlike Doublet

Figure 11. Rectangular Unlike Doublet

IV, A, Experimental Hardware and Test Setup (cont.)

(a) Unlike impingement of coherent jets is predicted to encourage freezing with LOX/RP-1 propellants.

(b) Coherent jets have less interfacial surface area and are not as active in promoting RSS.

(c) Spray angle and mixture ratio distributions will most likely vary with MR, P_c , and T_f .

The RUD injector was designed for the same operating conditions and propellants as the TL0L. The injection angles of 50° for the fuel and 20° for the LOX were selected so that the resultant spray fan would parallel the centerline of the chamber at nominal mixture ratio. Aspect ratios were chosen to keep orifice area and surface tension to a minimum, thus helping to avoid the change in free stream cross section from rectangular to circular. The L/D ratio for both orifices is greater than 6 in order to facilitate flowing fully attached (Ref. 3).

The inlet lines are fitted with "two-pass" coolant jackets to allow for switching propellant circuits. This switching flexibility allows the RUD to be used as a fuel rich gas generator element.

2. Hotfire Test Facility Setup

The test apparatus was setup in Test Bay 3 of the ALRC Research Physics Lab as shown in Figure 12. A schematic of the propellant system used is shown in Figure 13. Propellant was stored in one-gallon, 3000 psi run vessels. Gaseous pressurization of these systems was used to provide controlled run conditions over a wide range of chamber pressures. Gaseous helium was used to pressurize the LOX and gaseous nitrogen for the RP-1 and C_3H_8 .

Figure 12. Test Setup

PRESSURE
TEMPERATURE

Figure 13. Propellant Flow System Schematic

IV, A, Experimental Hardware and Test Setup (cont.)

LOX temperature conditioning was provided by means of the following: (1) LN₂ coolant jacket surrounding the LOX inlet line, (2) addition of a LOX bypass circuit to increase mass flow and keep LOX temperature low, and (3) chilling of the LOX thrust chamber valve with an LN₂ jacket. Both RP-1 and Propane were fired at ambient temperature conditions.

Four separate purges were employed during testing as follows: (1) a helium trickle purge was connected to the oxidizer circuit to prevent contamination or propellant migration, (2) a nitrogen purge was connected to the fuel circuit for the same reason, (3) a separately regulated GH₃ purge was used to provide chamber back pressure as well as provide window purge for the chamber viewports during the start and shutdown transients, (4) a separately regulated GN₂ supply was used to purge the test chamber after shutdown.

3. Cold Flow Test Setup

The cold flow tests were also conducted in the ALRC Research Physics Laboratory. Filtered, de-ionized water was used as the test fluid on most tests. Pressure measurements were made using Heise pressure gages and flow rate was measured using a time/volume technique, with run times of from 60 to 200 seconds. Strobe light photographs were taken of some of the injector flow tests to better evaluate propellant stream properties (see Section IV,C for photos).

4. Hot Fire Instrumentation

The high frequency and low frequency instrumentation listed in Tables I and II were used in the locations shown in the schematic of

IV, A, Experimental Hardware and Test Setup (cont.)

Figure 14. Low frequency response test parameters were recorded on a Consolidated Electrodynamics Corporation's direct writing oscillograph. High frequency response data were recorded on a Sangamo Model 3564 analog tape recorder.

Propellant flowrates were measured both by flowmeter and by using injector cold flow Kw's and the measured injection pressure drops. The pressure drops were electronically determined from the POJ, PFJ, and Pc transducers. Transducer bias and zero offsets were accounted for by pretest calibration.

The test operating point data were digitized and processed in an on-line HP 2100A computer. The Physics Lab data reduction program for the N₂O₄/Amine test program was modified for use with LOX/HC type propellants (see Appendix A). Curve fits for various LOX/HC properties such as viscosity, surface tension, density, etc. have been incorporated over the range of anticipated temperatures and pressures (see Appendix B). Figure 15 shows the input to the program and the formulas for the calculations to be made.

B. PHOTOGRAPHIC EQUIPMENT AND TECHNIQUES

The method of photographic characterization initially used was that found to be successful on the N₂O₄/MMH "Blowpart" program. Color high speed photographs of the spray field were taken at a rate of 800 pictures per second and an exposure time of 25 μ sec with a Hycam Model 41-0004 high speed camera (Figure 16). Ektachrome EF No. 7242 film (400 ft rolls) was used. The spray volume was illuminated with one 1000-watt quartz iodine lamp for back lighting and four 750 watt lamps for sidelighting.

Subsequent testing showed that this method was not capable of

IV, B, Photographic Equipment and Techniques (cont.)

"masking" the bright LOX/HC combustion light and "seeing" into the atomization and mixing process. It was soon discovered that one successful light setting would not be possible for each of the test conditions, as was the case during the Storable Propellant Blowapart program. Instead it was necessary to vary the f-stop, camera speed, and external lighting intensity depending on the chamber pressure, fuel type, and mixture ratio. Consequently a new flashbulb lighting technique was employed which proved much more effective in taking clear, discernible photographs. Each of the incandescent photo-floods was replaced with a large flashbulb (6 megalumen on the two front lights and 2 megalumen for the top, bottom, and back lights). The flashbulbs were triggered during steady state combustion just before shutdown and provided 25 ms of extremely bright light at a film speed of 3200 fps and an f-stop of 16. This technique proved to be much more effective in masking combustion light and seeing into the mixing process than the previous lighting arrangement.

C. TEST RESULTS

A total of 44 hotfire tests of three injectors (OFO, TLOL and RUD), and two fuels (RP-1 and Propane) were conducted between 1 March 1979 and 13 June 1979. Cold flow tests were also conducted to determine the injector element hydraulic resistances and to characterize non-reactive impingement phenomena.

1. Cold Flow Test Results

Each of the injectors were cold flow tested to determine their hydraulic resistance and to verify impingement accuracy. The cold flow tests were conducted in the Research Physics Laboratory. Filtered, de-ionized water was used as the test fluid on most tests. Pressure measurements were made using Heiss pressure gages and flow rate was calculated using a time/volume technique, with run times of from 60 to 200 seconds. Strobe light photographs were taken of the elements to evaluate propellant stream properties.

The hydraulic resistances were determined for each of the elements from plots of flowrate versus pressure drop as shown in Figures 17

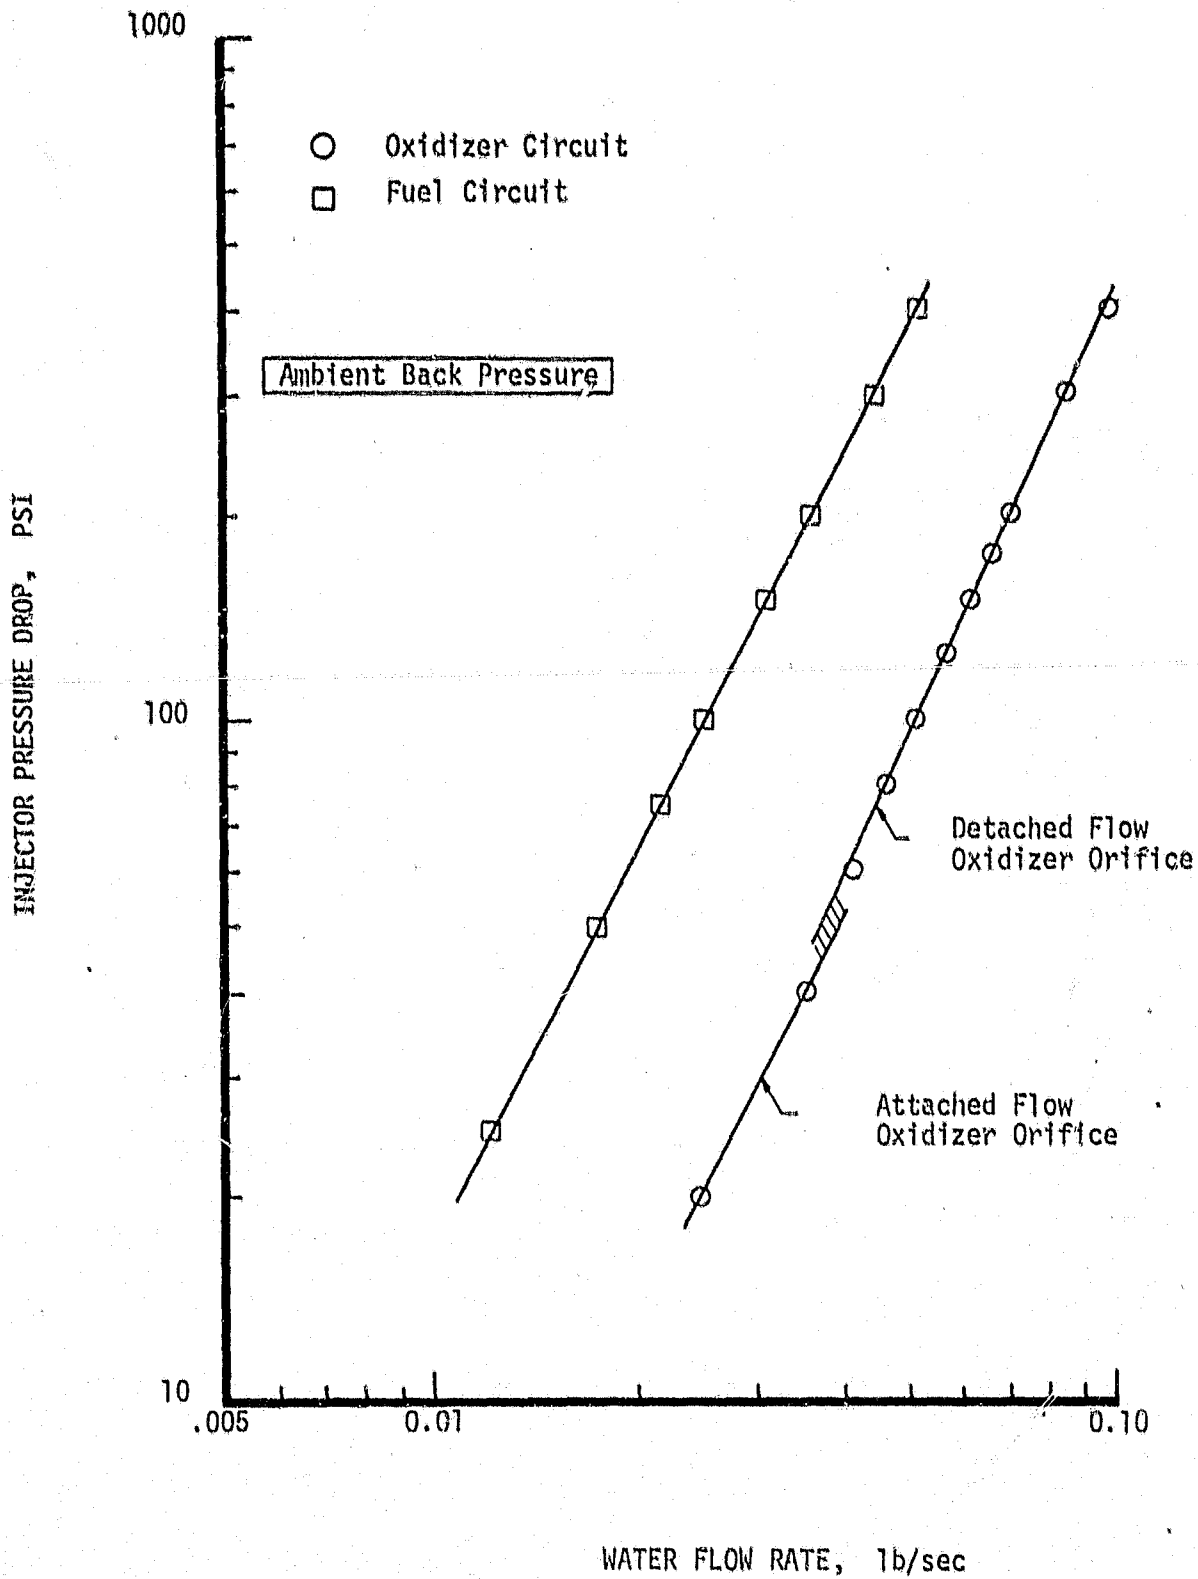

Figure 17. Pressure Drop Characteristics of the OFO Triplet

IV, C, Test Results (cont.)

through 19. Since the RUD injector element was damaged and repaired it was re-cold flowed. A plot of flowrate vs pressure drop for the repaired RUD element is superimposed on Figure 19. The resistance values for the three injectors are shown in Tables III through V.

The OFO triplet was residual hardware from Contract NAS 9-14186 and was shelved for a year after its original cold flow in January 1978. It was re-cold flowed in January 1979 (Figure 17) and yielded results which agreed within approximately 11% of the previous results. In both cases the fuel orifice flowed detached (due to cavitation) at pressure drops above 50 psi. This detachment phenomena did not occur during hotfire because of the increased back pressure. One of the oxidizer jets misimpinged very slightly during cold flow, but the spray fan still appeared to be well mixed.

The TL0L injector element was flowed both as a platelet stack and as a complete injector assembly with similar results. Figure 20 shows the unlike fan impingement of the TL0L at a pressure drop of 40 psi.

The RUD injector element was cold flowed twice because of damage sustained during hotfire testing (see Figures 21 and 22). After being repaired the RUD demonstrated Kw values and mixing qualities very similar to those obtained with the original injector. Figure 23 illustrates the coherent, rectangular jets and the well mixed spray fan obtained from the RUD during cold flow.

2. Hot Fire Test Results

A total of 44 hot fire tests of three injectors (OFO, TL0L, and RUD), and two fuels (RP-1 and Propane) were conducted between 1 March 1979 and 13 June 1979. The original OFO test matrix from Ref. 4 and the

IV, C, Test Results (cont.)

original test matrix for the TLOL and the RUD from Ref., 5 are shown in Tables VI and VII respectively. The test results along with pertinent comments are summarized in Table VIII. Included in Table VIII is a description of the chamber pressure, type of element, mixture ratio, injection velocities, propellant temperatures, and a list of symbols. Photographs taken from selected tests are shown in Figure 24 (13 pages). These photos are blowups of the high speed 16 mm movie film and will be of assistance in understanding the discussion which follows.

A total of sixteen tests were conducted with the OFO triplet using RP-1 as fuel. The chamber pressure was varied from 450 psia to 1505 psia while the mixture ratio varied from 1.7 to 2.8. These tests were dedicated to checking out the facility and photographic equipment and firming up a successful photographic technique.

Test results showed a very overexposed, turbulent combustion with an extremely bright central flame. There was far too much combustion light to see any droplet details using the baseline camera settings (ASA 125 film, shutter = 1/50, 800 pps, f4). After some test stand and light setting changes the movies showed greater detail, but showed a need for increased external light. The bright central flame which was white in earlier films appeared as a yellow flame interspersed with brownish areas which likely represent decomposing RP-1 and carbon formation. There appeared to be an RSS type of phenomena as evidenced by striations in the spray.

The final OFO tests during early April indicated that the light settings in use represented the optimum to be obtained from conventional photo-flood lighting. Test 114, at 1000 psia and MR = 2.35, appears as a bright central yellow flame interspersed with decomposing RP-1 and carbon formation. Test 116, at 1500 psia and MR = 2.6, differs from Test 114 only in its greater brilliance.

IV, C, Test Results (cont.)

A total of fifteen tests were conducted with the TLOL injector element using both RP-1 and Propane as fuel. TLOL testing utilized the flashbulb lighting technique described in Section IVB which greatly improved picture quality.

The TLOL combustion using RP-1 as fuel was similar to that of the OFO triplet with regards to: (1) coking, (2) lack of freezing or popping, (3) increasing brilliance with increasing chamber pressure, and (4) recirculation gas flow patterns. Dissimilarities in the spray field uniformity were observed due to differences in mixing characteristics. Both type of elements appear to exhibit RSS. The fuel fan was a brownish-black color even before unlike impingement, indicating thermal decomposition due to propellant stream heating. The LOX fans were a white-gray color and vaporized more rapidly with increasing chamber pressure.

The TLOL was then tested with Propane in order to gain an early comparison with the LOX/RP-1 data. The movies showed a much less brilliant combustion flame which produced much less carbon-particle emission than the LO₂/RP-1 combustion. The fuel fans were a grayish-brown color before unlike impingement indicating less thermal decomposition than the RP-1. Combustion light also increased with chamber pressure, but to a lesser degree than with LOX/RP-1. A brownish vapor is visible in the low pressure tests, resulting from propane's high vapor pressure. In comparison with the RP-1 tests carbon decomposition or sooting in the chamber was negligible.

The RUD injector element was scheduled to be tested with both RP-1 and propane, but facility problems arose which only left time for propane testing. Seven tests were fired with the RUD operating as a main chamber element. These tests covered a chamber pressure range from 150 psia to 800 psia and were markedly different from the TLOL LOX/C₃H₈ tests. These movies were darker than the TLOL LOX/C₃H₈ tests even though the

IV, C, Test Results (cont.)

lens was opened two stops. Much less mixing and combustion was in evidence near the injector face than with the TLOL or the OFO triplet. Swirling dark clouds near the injector face obscured the impingement interaction. The external lighting did not yield the same quality of picture as with the TLOL and OFO triplet, because the vapor and unburned combustion intermediates formed a sort of opaque mixture which wouldn't allow the penetration of external light. This lighting problem is due to the low vapor pressure of propane and RSS effects which modify the mixing characteristics of the RUD injector. A description of the degree of RSS demonstrated by the RUD element is difficult because the impingement is obscured and the chamber is filled with dark clouds.

The fuel and oxidizer circuits were then switched on the RUD so that it would be tested at fuel rich gas generator conditions. The first valid test (No. 143) fired for 2 seconds at $P_c = 860$ psia and $MR = 0.55$. Excessive sooting was experienced and the window inserts needed to be replaced (carbon deposits were cooked onto the glass and couldn't be removed). The windows were completely black and no photographic data was gained. Test 144 was a repeat of test 143 using conventional lighting for a comparison. After ignition the chamber filled with soot immediately and nothing more could be seen.
