Abstract

Background Epidural analgesia as the pain management for abdominal surgery has side effects such as paraesthesia, hypotension, haematomas, and impaired motoric of lower limbs. The quadratus lumborum block (QLB) has potential as an abdominal truncal block, however, the analgesic efficacy of QLB compared to epidural analgesia is unknown. This prospective randomised controlled study compared the effectiveness of QLB on postoperative opioid requirement and pain intensity with the epidural analgesia technique in transperitoneal laparoscopic nephrectomy. Methods Sixty-two patients underwent laparoscopic donor nephrectomy were randomised to receive QLB (n=31) or continuous epidural (n=31). The QLB group received bilateral QLB with 0.3–0.4 ml/kg bupivacaine 0.25% and the epidural group received bupivacaine 0.25% 6 ml/h for intraoperative analgesia. As postoperative analgesia, the QLB group received repeated bilateral QLB and the epidural group received the decreased dosage of bupivacaine 0.125% 6 ml/h for 24 hours after surgery completion. The primary outcome was cumulative morphine requirement 24 hours postoperatively. Secondary outcomes included haemodynamic changes, postoperative pain scores, sensory block coverage, Bromage score, postoperative nausea and vomiting (PONV), and duration of urinary catheterisation. Result Postoperative cumulative morphine requirement, pain scores, PONV and Bromage score were not significantly different between the QLB and epidural group. The QLB affected T9–L2, continuous epidural block affected T8–L3 dermatomes. Duration of urinary catheterisation was shorter ($p < 0.001$) in the QLB group. The mean arterial pressure (MAP) measured at 24 hours after surgery was lower in the epidural group ($p = 0.001$). Conclusion The repeated QLB had similar cumulative 24-h morphine requirement, higher MAP, similar postoperative pain scores, similar PONV and degree of motor and sensory blockade, and shorter urinary catheterisation duration, compared with continuous epidural analgesia after transperitoneal laparoscopic nephrectomy. Trial Registration ClinicalTrial.gov NCT03520205 retrospectively registered on May 9th 2018.

Background

Postoperative pain management holds an important role in laparoscopic living donor nephrectomy patient's recovery. The management of postoperative pain remains a major concern because some patients still demonstrated moderate to severe acute pain not different between laparoscopic or open nephrectomy.^{1,2} The pain after laparoscopic surgery consists of incisional wound pain, deep intra-abdominal pain and referred shoulder pain. Patients undergoing laparoscopic donor nephrectomy reveal the significant pain related to the Pfannenstiel incision and the deep intra-abdominal after surgery.³

The analgesic modalities for laparoscopic nephrectomy are epidural analgesia, intravenous patient-controlled analgesia (PCA) opioid, or the combination of both techniques. Epidural analgesia as the gold standard for abdominal surgery, however, has unfavorable side effects such as paraesthesia, hypotension, haematomas, impaired motoric of lower limbs and urinary catheterisation that could delay recovery. Opioid also has potential side effects such as sedation, pruritus, nausea, vomiting, and respiratory depression.⁴

Blanco and colleagues in 2007 first introduced quadratus lumborum block (QLB) as the posterior abdominal wall block by injecting local anaesthetic in the interfascial plane at the anterolateral margin of the quadratus lumborum muscle (the lateral QLB) under ultrasound guidance and then modified the point of injection into the posterior wall of the quadratus lumborum muscle (the posterior QLB) for postoperative analgesia after caesarean delivery.⁵ Børglum and colleagues refined the transmuscular approach by adopting the posterior approach to the QL block, using the 'Shamrock' sign from the erector spinae, quadratus lumborum and psoas muscles being the leaves and the transverse process of L4 as the stem and placing the needle tip anterior to the quadratus lumborum muscle. This approach is known as the anterior QLB by injecting local anaesthetic agent into the plane between the quadratus lumborum and psoas muscles resulted in reliable spread to the thoracic paravertebral space.⁶

The QLB became an alternative to epidural analgesia in reducing postoperative opioid requirements and pain intensity without central neuraxial block side effects in abdominal surgery.^{5,7} However, the efficacy of QLB as perioperative pain management in transperitoneal laparoscopic nephrectomy is unclear. Therefore, this study compared the effectiveness of QLB on decreasing postoperative opioid consumption and pain intensity with epidural analgesia in donor patients following transperitoneal laparoscopic nephrectomy.

Methods

Patients and study design

This prospective open-label randomised controlled study adheres to CONSORT guideline. This study was approved by the Ethics and Research Committee of Universitas Indonesia (0211/UN2.F1/ETIK/2018) and was retrospectively registered in [ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT03520205) (NCT03520205) on May 9th, 2018. Written informed consents were obtained from all adult patients with American Society of Anesthesiologists (ASA) I–II who underwent laparoscopic living donor nephrectomy in Cipto Mangunkusumo Hospital, DKI Jakarta. The inclusion criteria included age 18–60 year with body mass index (BMI) < 30 kg/m². The exclusion criteria included inability to communicate, history of allergy or contraindication to local anaesthetics, contraindication to epidural or QLB (coagulopathy or infections on the injection site).

The research protocol was explained to the patient who met the inclusion criteria. All patients were educated about QLB and continuous epidural procedures, how to describe the degree of pain with numerical rating scale (NRS), and how to use the PCA morphine pump when the pain level (NRS) \geq 4 after the surgery. After obtaining written approval, the patients were randomised either into the QLB group (intervention group) or the epidural group (control group). Randomisation was conducted in block sizes of 4 using a computerised randomisation sequence by independent research assistants. Randomisation allocation number for each subject was written on paper and put in a closed envelope. The envelope was opened by the anaesthesiologist who was appointed to perform epidural or QLB for this study. Primary investigators and statisticians were blinded to data collection throughout the study.

Technique for Epidural, Quadratus Lumborum Block and Pain Management

Standard monitoring was placed such as electrocardiogram, oxygen saturation, non-invasive blood pressure monitors and cardiometry ICON™. General anaesthesia induction was conducted with administration of fentanyl 2 µg/kg as co-induction, proceeded with propofol 1–2 mg/kg. Endotracheal tube intubation was facilitated with atracurium 0.5 mg/kg. The ventilator was set to volume control with positive end-expiratory pressure 5 cmH₂O and FiO₂ 30–50%, breathing frequency was adjusted with ETCO₂ target of 35–45 mmHg. The anaesthesia was maintained using sevoflurane with 2.5% minimum alveolar concentration, oxygen compressed air ratio of 40:60, atracurium 0.5 mg/kg/hour, with bispectral index target of 40–60, 0.8 for fraction of inspired sevoflurane, and train of four ratios 25%. All subjects received fentanyl 1 µg/kgi.v. if there is an increase of change in systolic blood pressure or pulse rate > 20% from the initial value during surgery and the total intraoperative fentanyl usage was recorded. Ephedrine was given if there is a decrease in mean arterial pressure (MAP) less than 65 mmHg during the study observation.

Two experienced anaesthetist consultants (P, DA) who was blinded to data collection during the study performed all the thoracic epidural and QLB procedures. Patients in the epidural group had an epidural catheter placement procedure in the left lateral decubitus position after intubation under general anaesthesia. After ensuring skin asepsis and draping the area with a sterile cover, an 18G Tuohy epidural needle was inserted in vertebral interspace T10–11 and catheter was advanced 5 cm length within the epidural space.⁸ We observed vacuum epidural catheter aspiration and a test dose of 3 ml bupivacaine 0.25% with adrenaline 1:200,000 without any change in pulse rate or blood pressure to confirm the position of catheter within the epidural space. Then a continuous epidural infusion of bupivacaine 0.25% 6 ml/h was maintained for intraoperative analgesia. For 24 hours postoperative pain management, after completion of the surgery the continuous epidural dosage was decreased into bupivacaine 0.125% 6 ml/h at the beginning and the dose was increased in 2 ml/h increments up to 10 ml/h if the pain is uncontrolled on PCA morphine setting (See Additional File 1).

All patients in the QLB group received the first bilateral ultrasound-guided transmuscular QLB (anterior QLB or QLB3) after induction and intubation under general anaesthesia for intraoperative analgesia. Patients were in supine position with the site to be blocked slightly facing upward by pillow underneath it and table tilting. After ensuring skin asepsis of the area, a 2.0–5.5 MHz convex transducer (C5-1E, DC-70, Mindray, Shenzhen China) covered with sterile drapes attached to the inferior lumbar (Petit's) triangle that consisted of iliac crest in the inferior region, the latissimus dorsi muscle in the posterior region and external abdominal oblique muscle in the anterior region). The Shamrock sign appeared on the ultrasound, then a 21G 100-mm peripheral block needle (Stimuplex®, BBraun, Mesulngen Germany) was inserted in-plane with ultrasound probe passing in anterior to posterior direction through the QL muscle and reached the border between the QL and psoas major muscle. After confirming negative for blood aspiration, 1 ml normal saline was injected to obtain hydrodissection sign for verifying the needle tip,

then a volume of 0.3–0.4 ml/kg bupivacaine 0.25% with a maximum of 25 ml was injected on each side (Figure 1). For 24 hours postoperative analgesia, the second bilateral QLB procedures were repeated one time at the end of surgery, with the same regimen of 0.3–0.4 ml/kg bupivacaine 0.25% with a maximum of 25 ml on each side.

[Figure 1]

Neostigmine 0.04–0.07 g/kg was given to reverse residual neuromuscular block and patient was extubated when had reached train of four ratio of 0.9–1.0. In the recovery room, patient-controlled morphine i.v. was administered using a portable programmed pump (Perfusor Space PCA Infusion Pump System, BBraun, Germany). The PCA setting was 1 mg bolus, lockout time 10 minutes and maximum dosage 6 mg/hour, without basal opioid infusion. All patients were informed how to use the PCA; first at preoperative anaesthesia visit and once again at the recovery room after the surgery. Ondansetron 4 mg i.v. and omeprazole 40 mg i.v. were administered every 12 hours to prevent postoperative nausea and vomiting (PONV).

Study parameters and statistical analysis

The aim of this study was to compare the analgesic efficacy of QLB with continuous epidural analgesia on postoperative morphine requirement and pain scores with numerical rating scale (NRS). The primary outcome was cumulative morphine requirement in 24 hours after surgery. The secondary outcomes were hemodynamic changes, pain scores at rest and movement, and motoric block at time points 2, 6, 12 and 24 hours after anaesthesia recovery. The MAP, heart rate, and cardiometry cardiac index were recorded at baseline, during surgery, and 24 hours after anaesthesia recovery. Pain scores were assessed using NRS (0 = no pain; 1–3 = mild pain, 4–6 = moderate pain, 7–10 = severe pain). Motoric block was evaluated using Bromage score (grade 1 = free movement of leg and feet; 2 = just able to flex knees with free movement of the feet; 3 = unable to flex knees, free movement of feet; 4 = unable to move the legs or feet). Sensory block was assessed after anaesthesia recovery using pinprick and cold loss sensation with ice and alcohol. Time to first morphine requirement, urinary catheterisation duration, PONV, and paraesthesia that occur within 24 hours postoperatively were recorded. Those outcomes were documented by the acute pain service team and ward nurses.

Sample size calculation was based on the primary hypothesis that opioid requirement in 24 hours after surgery. Based on the previous study, the mean (SD) cumulative morphine requirement 24 hours after surgery was 4 mg (SD = 4.723).⁹ From a preliminary study, the mean (SD) cumulative morphine requirement 24 hours after surgery was 4 mg (SD = 6.09). The reduction of 20% in cumulative morphine requirement was considered as clinically relevant. A sample size of 28 patients in each group was determined with a statistical power of 0.8 and type-1 error of 0.05. This study recruited 62 patients to allow 10% dropouts.

All statistical studies were analysed using Statistical Package for the Social Sciences (SPSS) version 20 (IBM Corp, Armonk, NY). Differences between numerical variable were analysed using the unpaired t-test for normal distribution data and Mann-Whitney test for abnormal distribution data. Differences between categorical variable were analysed using Chi square test. Numerical data with normal distribution was displayed in a mean (standard deviation), abnormal distribution was displayed in the median (interquartile range) values, and as percentage for categorical variables. The analysis was statistically significant if the p -value was less than 0.05.

Results

We enrolled 62 patients who met the inclusion criteria and signed the informed consent to take part in the study from May to August 2018. The subjects were randomly assigned into two groups and received their allocated intervention. None of the subjects were excluded from the study; therefore, all patients were followed-up and included in the final analysis (Figure 2). Between the QLB and epidural group, the demographic baseline and perioperative characteristics of the study subjects were similar. Intraoperative fentanyl requirement was not significantly different between the two groups. However, ephedrine requirement was higher in the epidural group compared to QLB group (0 (0 – 50) vs 10 (0 – 50) mg, $p = 0.026$) (Table 1). The mean total dosage of bupivacaine used in the QLB group was significantly lower than the epidural group (Table 1).

[Figure 2.]

Intraoperative MAP, heart rate and cardiac index (Figure 3) were not significantly different between the QLB and epidural group, however, postoperative MAP measured at 24 hours after surgery was significantly lower in the epidural group 72.26 (67.69–76.83) mmHg than those in QLB group 83.33 (78.72–87.95) mmHg ($p = 0.001$) (See Additional file 2).

[Figure 3.]

Figure 4 shows the cumulative morphine requirement at each time point in 24 hours after surgery were comparable between the QLB and epidural group. Time to first morphine initiation using PCA were not significantly different between the QLB and epidural group (120 (0 – 1170) vs 125 (0 – 1080) minutes, $p = 0.703$) (See Additional file 3). There were 3 subjects in the QLB group and 4 subjects in the epidural group did not need additional morphine at all in 24 hours after anaesthesia recovery.

[Figure 4.]

Pain scores at rest and in movement at each time point in 24 hours after anaesthesia recovery were not significantly different between the QLB and epidural group. The lowest pain scores at rest and in

movement were at 2 and 6 hours after anaesthesia recovery in both groups. The Bromage scores were not significantly different between the groups. Only 1 subject complained paraesthesia in the epidural group. The incidence of PONV in the QLB group was not significantly higher than the epidural group. Subjects in the QLB block group had a significantly shorter duration of urinary catheterisation than the epidural group (Table 2).

The bar in Figure 5 shows the variable degree of sensory block spread in both groups. The majority of patients in the QLB group had loss of cold and pinprick sensations from T10 to L2, compared with the majority of patients the epidural group had loss of cold and pinprick sensations from T9 to L2. None of the patients in QLB group showed sensory blockade on level T8 and L3. Block-related complications such as local anaesthetic systemic toxicity (LAST), bleeding, infection or neurological deficits, and epidural catheter-related problems such as dislodge, blocking, or leakage, were not found in this study.

[Figure 5.]

Discussion

Alper and colleagues described that patients undergoing laparoscopic or open nephrectomy had non-significant differences in postoperative acute pain scores, additional analgesia requirement, and were at equal risk of developing chronic postsurgical pain (CPSP) at 2 and 6 months after surgery.² Clinical trials of QLB are still limited, but evidence has shown the efficacy of QLB in reducing opioid requirement after caesarean section, laparotomy, laparoscopic procedure, and hip surgery.¹⁰⁻¹² In 2017, Corso and colleagues reported a case of QLB as postoperative pain management after open nephrectomy.¹³ Pain management is important in order to reduce postoperative pain, promotes recovery, and prevent CPSP in living donor patients. Our study was the first randomised controlled trial that compared the analgesic efficacy of bilateral QLB compared with continuous epidural analgesia following transperitoneal laparoscopic living donor nephrectomy.

Compared with the QLB group, MAP in epidural group patients were lower and required more ephedrine during observation. Epidural analgesia has unfavourable side effects such as hypotension especially in patients at risk of hemodynamic instability. It directly inhibits the sympathetic nervous system and decreases vasomotor tone resulting in vasodilation that corresponds to decreased MAP values in the epidural group.¹³ Zhu and colleagues found the combination of thoracic epidural and general anaesthesia had lower systolic, diastolic and pulse pressure compared with general anaesthesia alone in laparoscopic cholecystectomy.¹⁴

Blanco and colleagues performed QLB using 0.2 ml/kg 0.125% bupivacaine in which showed a significant reduction in morphine requirement and visual analogue scores for 48 hours after caesarean delivery. The QLB also showed a superior effect of analgesia lasting from 6 to 48 hours compared with TAP block.⁵ In our study, patients receiving pre- and postoperative QLB using 0.3–0.4 ml/kg 0.25%

bupivacaine showed comparable cumulative morphine requirement compared with patients receiving continuous epidural analgesia using 6 ml/hr 0.125% bupivacaine for 24 hours postoperatively. The intraoperative fentanyl consumption was also not significantly different between the two groups.

Pain scores at rest and in movement were not significantly different between both groups, suggesting the QLB had comparable analgesic effect with continuous epidural analgesia during the 24 hours after anaesthesia recovery. The transmuscular QLB (anterior QLB or QLB3) facilitates spread of local anaesthetic into the thoracic paravertebral space, produces prolonged block from 6 to 48 hours and achieving visceral pain relief similar to epidural block. Although this spread has not been clearly proven, the QLB has the potential to provide both somatic and visceral analgesia.⁶ The local anaesthetic spreads to the thoracolumbar fasciae that extensively innervated A- and C-fibre nociceptors and mechanoreceptors. Therefore, it has a direct effect to lower these high-density sympathetic fibres activity that explains the longer analgesic effect of the QLB.¹⁵ We found pain level assessment was challenging. The PCA morphine after surgery was intended to treat surgical pain, but urinary catheter discomfort also became a trigger for the patient to use PCA. Pain characteristics and levels of anxiety after surgery was varied between individuals also considered affecting morphine requirement especially in early postoperative period.¹⁶⁻¹⁹

In our study, the dermatomal coverage of QLB from T10 to L2 was lower compared to the QLB coverage from T7 to T12 in a study by Murouichi and colleagues.¹¹ The Pfannenstiel incision is the most significant determinants of postoperative pain after laparoscopic nephrectomy,³ therefore, the spread of local anaesthetic covered the dermatome area of the incisions and the analgesic effect was sufficient for surgical wound pain relief, in accordance with the Pfannenstiel incision whose dermatomes T12–L1.^{2,20} The dye studies in cadavers and MRI studies in volunteers demonstrated thoracic spread because penetration of quadratus lumborum and anterior thoracolumbar fascia was more antero-laterally and may be associated with a more extensive cephalad distribution. Those findings support that although local anaesthetic was injected at L4 level, no sensory blockage was found in L3 and L4 levels.²¹

The increasing perioperative opioid requirement increases the incidence of PONV and postoperative urinary retention (POUR).^{22,23} In our study, the incidence of PONV was not significantly different, since there was no significant difference in perioperative opioid requirement between the two groups. Patients receiving QLB showed a significant shorter duration of urinary catheterisation than patients with continuous epidural analgesia. Early removal of the urinary catheter when is no longer needed is recommended regarding postoperative early recovery because longer urinary catheterisation can affect mobilisation.²⁴ However, we noticed that some surgeons decided to remove the urinary catheter after the discontinuation of epidural analgesia due to the concern of urinary retention. Epidural analgesia acts on lumbar and sacral nerve fibres and blocks the bladder detrusor function. In our study, none of the patients in epidural or QLB group required urinary re-catheterisation, was different from the study by Niraj and colleagues that found more patients receiving continuous epidural analgesia required urinary re-catheterisation due to urinary retention compared to patients receiving continuous TAP block after

laparoscopic colorectal surgery. Hayami and colleagues demonstrated that urinary catheter removal before discontinuing epidural analgesia had higher incidences of POUR regardless of the amount of opioid use.²⁵

The inconvenience from epidural catheter placement also inhibits patient mobilisation, while the QLB is performed by bilateral injections without catheter insertion.^{5,26} Both the QLB and epidural group showed similar absent of lower extremity motor blockade represented by the Bromage score (0 – 1). Assessment of limb motor strength is important which may be a sign of impending neurological deficits in epidural analgesia.²⁷ Paddalwar and colleagues reported that epidural using 0.125% bupivacaine had shown effective labour analgesia and reduced motor block intensity.²⁸ In our study, the QLB using 0.25% bupivacaine relieved pain in the abdominal area as effective as epidural analgesia without limb motor blockade.

From the technical aspects and safety perspective, the thoracic epidural analgesia is more challenging especially for the mid to high thoracic due to more acute angle of approach and narrower spaces compare to lower thoracic or lumbar level. Adequate practice of epidural analgesia skill by improving knowledge of anatomy, landmarks, using adequate local analgesia, midline or paramedian approach, and patient position can reduce the multiple needle insertion, inadequate analgesia and dural puncture incidence. The anaesthesiologist can become skillful at performing QLB after several practice of procedure. The sonoanatomic markers of the lateral (QLB1), posterior (QLB2) and intramuscular QLB are easy to find and safe to be performed in supine position. The anterior approach (QLB3) is considered as a more invasive technique which is better performed in lateral or slightly lateral position by experienced practitioners.²⁹

The optimal dosage of local anaesthetic for QLB is not known, and a higher dosage may have improved and prolonged the analgesic effect. Local anaesthetic systemic toxicity (LAST) was a concern as the QLB in our study was the bilateral high-volume blocks. However, the mean total bupivacaine requirement in the QLB group was significantly lower than the epidural group. We did not find any LAST symptoms during study observation, and the total dosage of local anaesthetic in both groups were lower than the recommendation for bupivacaine to not exceed 2.5–3 mg/kg or 175 mg per injection with maximum dosage 400 mg in 24 hours.³⁰⁻³²

Our study had several limitations. This study did not include a controlled group using i.v. morphine PCA alone. Given such low NRS pain scores and low 24 h morphine consumption, it was difficult to evaluate the true analgesic value of QLB and continuous thoracic epidural analgesia. There was a lack of blinding because of the QLB was bilateral injections without catheter inserted and the epidural block had a catheter inserted. However, those are the common approaches of the blocks. The spread of block was confirmed only once after anaesthesia recovery, and the analgesic efficacy of the two blocks was assessed only in 24 hours after anaesthesia recovery following the policy in our institution that retains epidural catheter only for 24 hours after laparoscopic surgery. The study subject was representative for the normal BMI population underwent laparoscopic nephrectomy in our institution, therefore,

generalisability is limited in other population such as obese patient or clinical context in which continuous QL block is available and epidural can be performed longer than 24 hours.

Conclusions

The QLB has potential as an alternative pain management following laparoscopic nephrectomy. The QLB had similar 24 h cumulative morphine requirement, higher postoperative mean arterial pressure, similar postoperative pain intensity, time of first analgesics, PONV, degree of motor and sensory blockade, and shorter duration of urinary catheterisation in comparison with continuous epidural analgesia after transperitoneal laparoscopic nephrectomy. Further studies of the QLB regarding the optimal dosage of local anaesthetic is needed.

Abbreviations

ASA: American Society of Anesthesiologists classification; BMI: body mass index; CPSP: chronic postsurgical pain; ES: erector spinae; HR: heart rate; L2, L3, L4: second, third, fourth lumbar vertebral body; LAST: local anaesthetic systemic toxicity; MAP: mean arterial pressure; NRS: numerical rating scale; PCA: patient-controlled analgesia; PM: psoas major; PONV: postoperative nausea and vomiting; POUR: postoperative urinary retention; QLB: quadratus lumborum block; SBP: systolic blood pressure; T7, T8, T9, T12: seventh, eighth, ninth, twelve thoracic vertebral body; TAP: transversus abdominis plane.

Declarations

Ethics approval and consent to participate

The study protocol was approved by the Ethics and Research Committee of Universitas Indonesia (0211/UN2.F1/ETIK/2018; protocol no: 18-03-0260; approval date: March 12th, 2018) and was retrospectively registered on May 9th, 2018 in [ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT03520205) (NCT03520205). Written informed consent to participate was obtained from each participant. No organs or tissues were obtained from participants.

Consent to publish

Not applicable.

Tables

Table 1. Patient baseline and perioperative characteristics.

Variables	QLB group (n = 31)	Epidural group (n=31)	<i>p</i> value
Sex			1.000
Men (%)	21 (67.74)	20 (64.51)	
Women (%)	10 (32.26)	11 (35.49)	
Age (years)	38.29 ± 12.97	39.97 ± 11.49	0.447
Body weight (kg)	64.34 ± 10.10	62.72 ± 10.06	0.530
Body height (cm)	164.06 ± 7.62	161.80 ± 8.74	0.277
BMI (kg/m ²)	24.06 ± 3.82	24.13 ± 4.06	0.940
ASA			0.794
ASA 1 (%)	18 (58.06)	20 (64.51)	
ASA 2 (%)	13 (41.94)	11 (35.49)	
Intraoperative fentanyl dosage (µg)	50 (0 – 250)	50 (0 – 400)	0.442
Intraoperative ephedrine dosage (mg)	0 (0 – 50)	10 (0 – 50)	0.026
Duration of surgery (minute)	285.6 ± 42.6	292.2 ± 44.4	0.551
Duration of anaesthesia (minute)	354.6 ± 36.6	357.6 ± 33.6	0.796
Total bupivacaine dosage (mg)	200.00 ± 19.00	253.18 ± 11.11	<0.001

QLB, quadratus lumborum block; BMI, body mass index; ASA, american society of anesthesiologist. Data are presented in number (percentage), mean \pm standard deviation or median (interquartile range)

Table 2. Postoperative pain scores and side effects of QLB versus continuous epidural analgesia.

Parameter	QLB group (n = 31)	Epidural group (n = 31)	p-value
NRS at rest after anaesthesia recovery			
Immediately	1 (0 – 5)	2 (0 – 7)	0.313
At 2 hours	2 (0 – 5)	2 (0 – 6)	0.785
At 6 hours	1 (0 – 5)	2 (0 – 4)	0.708
At 12 hours	2 (1 – 6)	2 (0 – 5)	0.659
At 24 hours	2 (0 – 4)	2 (0 – 5)	0.878
NRS in movement after anaesthesia recovery			
Immediately	3 (0 – 6)	3 (0 – 8)	0.617
At 2 hours	3 (0 – 6)	3 (1 – 7)	0.863
At 6 hours	3 (1 – 6)	3 (1 – 6)	0.868
At 12 hours	3 (2 – 8)	3 (1 – 6)	0.895
At 24 hours	3 (1 – 5)	3 (1 – 6)	0.873
Bromage score after anaesthesia recovery			
Immediately	1 (1 – 2)	1 (1 – 2)	1.000
At 2 hours	1 (1 – 2)	1 (1 – 2)	1.000
At 6 hours	1 (1 – 1)	1 (1 – 1)	1.000
At 12 hours	1 (1 – 1)	1 (1 – 1)	1.000
At 24 hours	1 (1 – 1)	1 (1 – 1)	1.000
Paraesthesia (%)	0 (0.00)	1 (3.22)	0.05
Postoperative nausea and vomiting (%)	7 (22.58)	5 (16.12)	0.07
Duration of urinary catheter (hours)	37.03 \pm 9.14	42.97 \pm 5.72	0.004

Data are presented as mean \pm standard deviation or median (interquartile range) or number (percentage).

Figures

Figure 1

Anterior quadratus lumborum block sonography. A. Patient and ultrasound probe position, a peripheral block needle was inserted in-plane under ultrasound guidance in anteroposterior direction. B. Shamrock sign appeared on the ultrasound, which was the transverse process of the L4 vertebra as a trunk, the posterior ES muscle, the anterior PM muscle, and the lateral QL muscle. B. The needle passed through the quadratus lumborum. White arrow indicates local anaesthetic deposition shown by the widening of hypoechoic between the QL and PM muscle, and needle trajectory. PM, psoas major; QL, quadratus lumborum; ES, erector spinae; L4, Vertebral body L4.

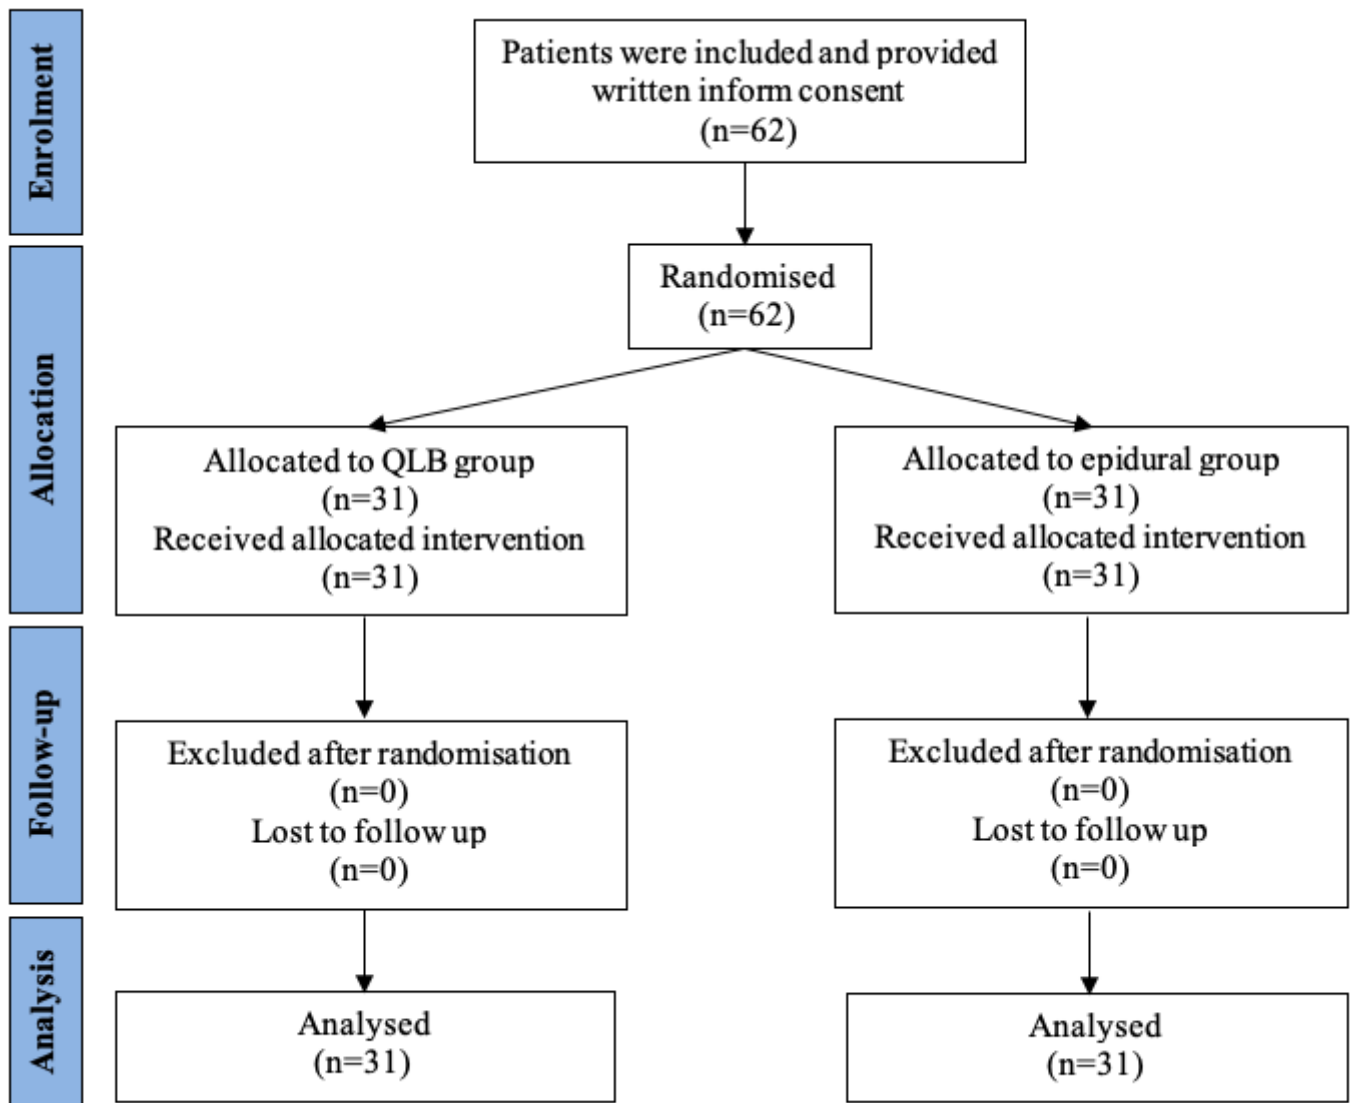

Figure 2

CONSORT flow diagram.

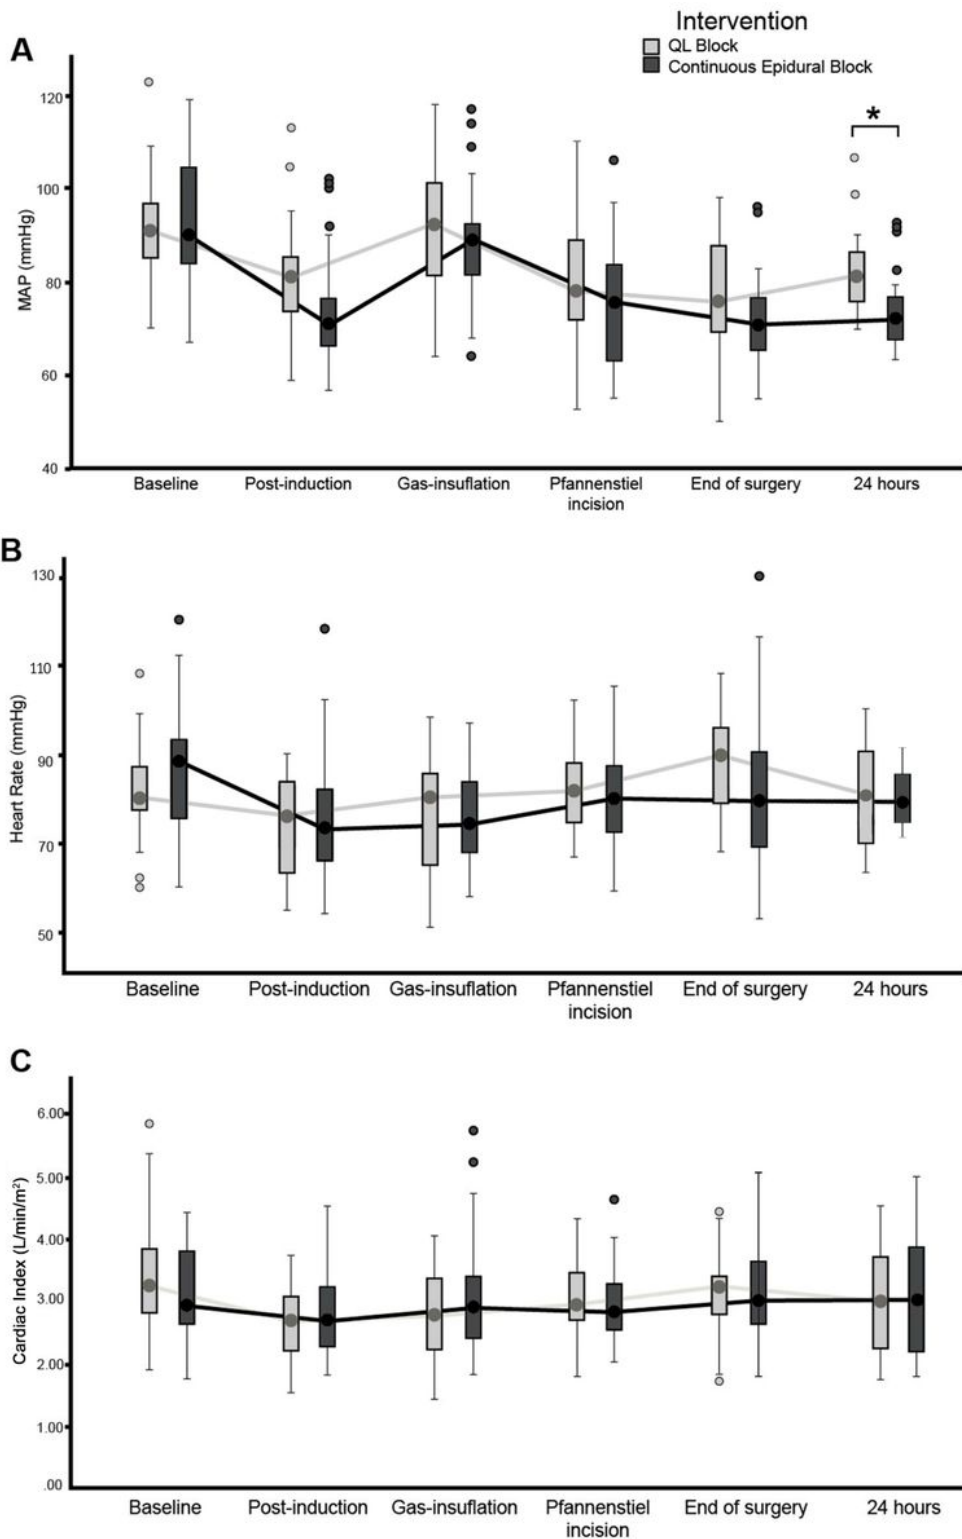

Figure 3

Intraoperative haemodynamic profile of QLB versus continuous epidural analgesia. The p-values were analysed using Mann-Whitney test, the horizontal lines indicate medians; boxes indicate interquartile range; whiskers indicate range. *p < 0.05 is significant. MAP, mean arterial pressure; bpm, beats per minute.

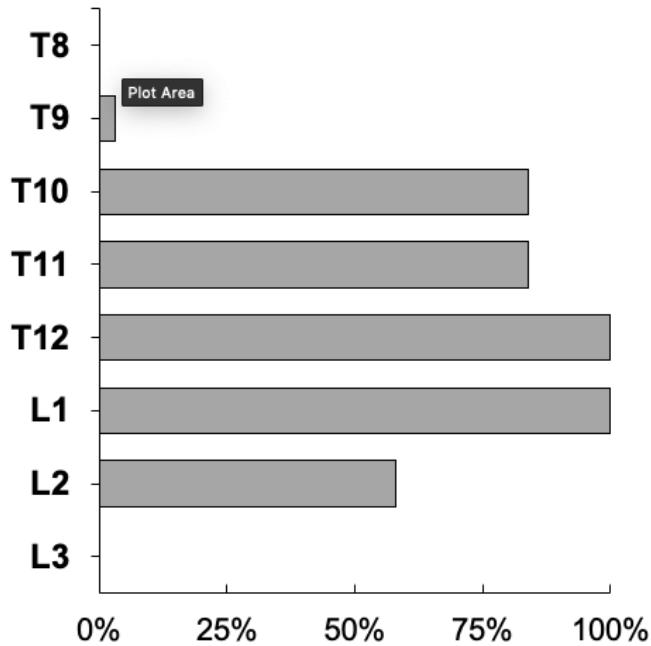

Figure 4

Cumulative morphine requirement of QLB versus continuous epidural analgesia. Median values of cumulative morphine requirement (mg) at each time point after anaesthesia recovery are as follows: 2 hours, 0 (0 – 3) to 0 (0 – 4) ($p = 0.857$); 6 hours, 2 (0 – 7) to (2 (0 – 9) ($p = 0.977$); 12 hours, 3 (0 – 13) to 3 (0 – 15) ($p = 0.764$); 24 hours, 3 (0 – 18) to 4 (0 – 18) ($p = 0.792$). The p-values were analysed using Mann-Whitney test, the horizontal lines indicate medians; boxes indicate interquartile range; whiskers indicate range.

QLB (n = 31)

Continuous Epidural (n = 31)

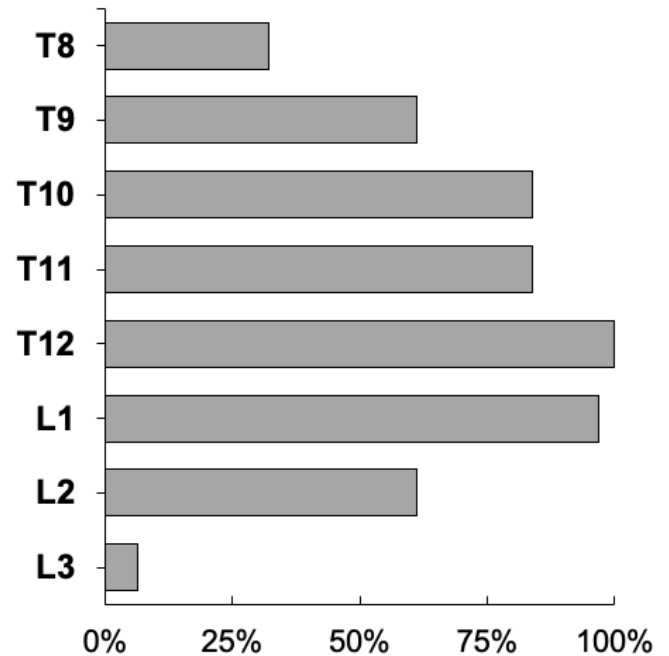

Figure 5

Dermatomal effects of QLB and continuous epidural analgesia. The QLB and epidural group showed similar percentage of sensory blockade on level T12–L1 (97–100%), T10–T11 (84%), L2 (58–61% of patients). The QLB group showed percentage of sensory blockade on level T9 (3% vs 61.3%), T8 (0% vs 32.3%), L3 (0% vs 6.5%) less than epidural group patients. QLB, quadratus lumborum block.
