Abstract. Large wildfires influence regional atmospheric composition, but chemical complexity challenges model predictions of downwind impacts. Here, we elucidate key connections within gas-phase photochemistry and assess novel chemical processes via a case study of the 2013 California Rim Fire plume. Airborne in

situ observations, acquired during the NASA Studies of Emissions, Atmospheric Composition, Clouds and Climate Coupling by Regional Surveys (SEAC⁴RS) mission, illustrate the evolution of volatile organic compounds (VOCs), oxidants, and reactive nitrogen over 12 h of atmospheric aging. Measurements show rapid formation of ozone and peroxyacyl nitrates (PNs), sustained peroxide production, and prolonged enhancements in oxygenated VOCs and nitrogen oxides (NO_x).

Observations and Lagrangian trajectories constrain a 0-D puff model that approximates plume photochemical history and provides a framework for evaluating process interactions. Simulations examine the effects of (1) previously unmeasured reactive VOCs identified in recent laboratory studies and (2) emissions and secondary production of nitrous acid (HONO). Inclusion of estimated unmeasured VOCs leads to a 250 % increase in OH reactivity and a 70 % increase in radical production via oxygenated VOC photolysis. HONO amplifies radical cycling and serves as a downwind NO_x source, although impacts depend on how HONO is introduced. The addition of initial HONO (representing primary emissions) or particulate nitrate photolysis amplifies ozone production, while heterogeneous conversion of NO₂ suppresses ozone formation. Analysis of radical initiation rates suggests that oxygenated VOC photolysis is a major radical source, exceeding HONO photolysis when averaged over the first 2 h of aging. Ozone production chemistry transitions from VOC sensitive to NO_x sensitive within the first hour of plume aging, with both peroxide and organic nitrate formation contributing significantly to radical termination. To simulate smoke plume chemistry accurately, models should simultaneously account for the full reactive VOC pool and all relevant oxidant sources.

1 Introduction

Biomass burning accounts for at least 30 % of global emissions of non-methane volatile organic compounds (VOCs; Akagi et al., 2011; Andreae, 2019; Yokelson et al., 2008). Pyrogenic VOC fuel production of ozone and secondary organic aerosol, with significant consequences for air quality and climate (Jaffe and Wigder, 2012; McClure and Jaffe, 2018; Buysse et al., 2019; Val Martin et al., 2015; Hodshire et al., 2019). Pyrogenic emissions consist of thousands of unique compounds. Existing emission inventories include over 100 individual VOCs (Andreae, 2019; Akagi et al., 2011). These compilations are incomplete, and it is estimated that previously unidentified VOCs account for ~ 50 % of total pyrogenic VOC mass (Akagi et al., 2011; Yokelson et al., 2013; Gilman et al., 2015). Recent advances in instrumentation have broadened the suite of detectable VOCs to over 500 species (Sekimoto et al., 2018; Hatch et al., 2017, 2019; Koss et al., 2018), although significant uncertainty remains regarding the speciation, reactivity, and fate of this extended VOC pool.

The photochemistry of biomass burning plumes is perhaps less well understood than emissions, especially within the context of total reactive VOC. Observations of ambient smoke typically encompass a few hours of physical age and include a limited set of compounds (Akagi et al., 2012, 2013; Alvarado et al., 2010; Liu et al., 2016; Müller et al., 2016). Detailed simulations may provide some insight into the chemistry of unidentified VOCs, though models are often under-constrained, and both model and measurement uncertainties can be large (Lonsdale et al., 2020; Alvarado et al., 2015; Müller et al., 2016; Mason et al., 2001; Liu et al., 2016). With extended VOC inventories from recent lab-

oratory work (Hatch et al., 2017; Koss et al., 2018), several studies have begun characterizing the impacts of previously unidentified VOC. Analyzing a series of laboratory burns, Coggon et al. (2019) estimate that the species included in the Master Chemical Mechanism (MCMv3.3.1) account for ~ 60 % of the primary hydroxyl radical (OH) reactivity measured via proton transfer time-of-flight mass spectrometry. This study also demonstrates that furans, a previously unconsidered class of reactive VOCs, may increase ozone (O₃) production within an agricultural fire plume by ~ 10 % over the first hour of aging. Decker et al. (2019) estimate that the MCM accounts for ~ 30 % of the observed nitrate radical (NO₃) reactivity in the same laboratory experiments.

Despite improved knowledge of pyrogenic VOC speciation, it remains unclear how to best synthesize this information within existing regional/global model frameworks. It is not feasible to add a multitude of new species to chemical mechanisms; indeed, many global models neither explicitly account for all known VOCs (Duncan et al., 2007; Wiedinmyer et al., 2011), nor is it evident that such modifications would improve model results, as plume chemistry may be a subgrid-scale process more suited to parameterization than explicit simulation. On the other hand, reactive VOC chemistry can persist for days downwind of a fire (Mauzerall et al., 1998; Alvarado et al., 2020; Forrister et al., 2015), and an improved representation of such processes may alter regional budgets of ozone, CO, oxidized VOC, reactive nitrogen, and organic aerosol.

Oxidant sources also remain poorly understood in this environment. Smoke plumes are photochemically complex due to spatial and temporal variability in radical precursors, radiation, and other factors (Wang et al., 2021). Recent work has highlighted the importance of emitted nitrous acid (HONO)

as a radical source in nascent smoke plumes (Peng et al., 2020; Theys et al., 2020; Robinson et al., 2021). Secondary HONO production via heterogeneous processes may sustain downwind radical production in some, but not all, smoke plumes (Alvarado and Prinn, 2009; Alvarado et al., 2015). Multiple mechanisms have been proposed to explain observed HONO in other environments (Zhang et al., 2019), but their controlling factors and potential impacts are not well characterized.

Here, we utilize a case study of the 2013 California Rim Fire to examine the impacts of newly identified reactive VOC and HONO on gas-phase chemistry. Airborne in situ observations from the NASA Studies of Emissions, Atmospheric Composition, Clouds and Climate Coupling by Regional Surveys (SEAC⁴RS) mission constrain the evolution of emitted gases, oxidants, and oxidation products over ~ 12 h of atmospheric aging. We combine these observations with air mass trajectories to drive a 0-D puff model that approximates plume aging. With this framework, we illustrate how an extended VOC pool and various HONO sources alter the chemistry of oxidants, oxidized VOC, reactive nitrogen, and ozone. We evaluate model results through comparison with observations and use the model to quantify age- and mechanism-dependent changes in OH reactivity, radical production/termination, and ozone production sensitivity to VOC and NO_x.

2 Methods

2.1 Rim Fire and SEAC⁴RS observations

The Rim Fire was an extreme wildfire in the central Sierra Nevada Mountains of California (37.85° N, 120.08° W). Ignited by an illegal campfire on 17 August 2013, the fire was not fully contained until 24 October 2013 and consumed a total area exceeding 1000 km². At the time of the SEAC⁴RS flights, the fire front spanned a width of ~ 40 km in both the N–S and E–W directions. Fuels consisted mostly of mixed conifer forest (Lydersen et al., 2014). Previous Rim Fire studies have investigated fire meteorology (Peterson et al., 2015), emissions (Liu et al., 2017; Yates et al., 2016; Saide et al., 2015), aerosol properties (Forrister et al., 2015; Adler et al., 2019; Perring et al., 2017), radiative effects (Yu et al., 2016), and regional chemistry model performance (Baker et al., 2018). We focus here on downwind gas-phase photochemistry.

SEAC⁴RS was a NASA-funded effort to characterize the processes controlling atmospheric properties in the summertime in the USA (Toon et al., 2016). We utilize in situ observations acquired from the NASA DC-8 aircraft, which sampled Rim Fire outflow on 26 and 27 August 2013. Analysis focuses on the long axis portion of the 26 August flight, which extends from directly over the fire to 470 km downwind (Fig. 1). The actual sample time window for this leg is 23:06 to 23:57 UTC, and the physical smoke age ranges

from 0 to ~ 12 h (Sect. 2.2). The aircraft maintained a pressure altitude of 4.3 km until 23:32 UTC (smoke age ~ 5 h), when it descended to 3.6 km (see Fig. S1 in the Supplement). The terrain was mountainous, and the corresponding altitude above ground level ranged from 1.3 to 3.2 km. Sampling was predominantly in the upper edge of the smoke plume and in the lower free troposphere, according to the boundary layer depth derived from trajectory meteorological fields (Fig. S1c). The modified combustion efficiency (MCE) near the source ranged from 0.91 to 0.94, indicating a mix of flaming and smoldering combustion. The DC-8 also sampled Rim Fire smoke as old as 2–3 d, but influence from other fires, surface–atmosphere exchange, and changing background concentrations complicate the analysis of that data. SEAC⁴RS also investigated several other wild- and agricultural fire plumes (Liu et al., 2016; Toon et al., 2016).

Table S1 lists the instruments and measurement accuracy for observations used in this study; the payload is further described in Toon et al. (2016). Here we provide a brief summary of the key measurements. Most speciated VOC observations (alkanes, alkenes, aromatics, terpenes, and alkyl nitrates) derive from the Whole Air Sampler (WAS), with a sample collection time of 40 s and a sampling interval of 2–10 min. We also use VOC and oxygenated VOC (oVOC) observations from the proton transfer quadrupole mass spectrometer (PTR-MS), including acetaldehyde, the sum of methyl vinyl ketone and methacrolein (MVK + MACR), and the sum of isoprene and furan. Furan is calculated as the difference between the PTR-MS sum and WAS isoprene. Formaldehyde (HCHO) is measured via both laser-induced fluorescence and infrared absorption spectroscopy. Peroxides, nitric acid, and hydroxynitrates are measured via CF₃O[−] chemical ionization mass spectrometry (CIMS). Other oxidized nitrogen measurements include NO and NO₂ via chemiluminescence, NO₂, total peroxy nitrates, and total alkyl nitrates via thermal dissociation (i.e., laser-induced fluorescence) and speciated peroxyacyl nitrates via thermal dissociation iodide CIMS. Ozone is measured via chemiluminescence. Carbon monoxide (CO) is measured via differential absorption. Photolysis frequencies are calculated from observed up- and down-welling actinic flux combined with the literature-recommended cross sections and quantum yields. Other observations used primarily for model inputs include pressure, temperature, water vapor (open-path absorption), particulate nitrate (aerosol mass spectrometer), aerosol surface area (laser aerosol spectrometer), and total solar irradiance. Aside from WAS data, observations are nominally reported at 1 Hz but may contain gaps due to normal instrument operation. For this analysis, all 1 Hz data are averaged to WAS collection windows. The dataset does not include observation of total oxidized nitrogen (NO_y), nitrous acid (HONO), or ammonia (NH₃).

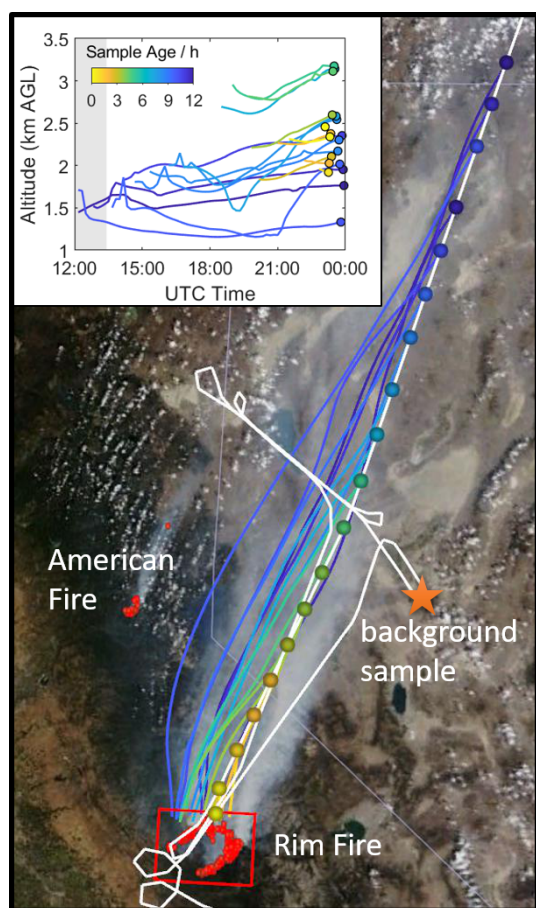

Figure 1. Map of the study region. The background shows visible imagery and fire counts (red dots) from Terra/MODIS (<https://worldview.earthdata.nasa.gov/>, last access: 23 January 2020). The white line is the DC-8 flight track. The aircraft entered from the south, flew over the fire, proceeded NE to do a missed approach at Fallon Municipal Airport (near orange star), executed a wall pattern of perpendicular transects at several altitudes, and returned to the fire before proceeding NE along the long axis leg. Colored circles denote the Whole Air Sampler (WAS) sample locations, and colored lines are the corresponding median trajectories. Yellow-to-blue shading indicates Lagrangian plume age at the time of sampling (see color bar in the inset). The orange star is the location of the background sample. The red box is the Rim Fire box used for trajectory filtering. The inset shows the time series of the median trajectory altitudes with respect to ground level. Colored circles denote the observation time. The gray shaded area indicates night time.

Normalized excess mixing ratios (NEMRs) are calculated using CO as the dilution tracer.

$$\text{NEMR}(X) = \Delta X / \Delta \text{CO} = (X - X_b) / (\text{CO} - \text{CO}_b). \quad (1)$$

Here, X is the observed mixing ratio and X_b is the background mixing ratio. Fast observations fluctuate rapidly in fire plumes and can sometimes contain gaps over a portion of a WAS sampling interval. We adopt a custom averaging procedure to ensure rigorous NEMR calculation for such data.

First, each 1 Hz variable X is time-aligned to CO by applying a time lag based on the maximum cross-correlation. Second, CO is filtered to exclude points where X is missing. Finally, X and the filtered CO are averaged to the WAS time base. Executing this procedure over all data effectively creates a unique, gap-filtered, WAS-averaged CO for each variable. Figure S2 shows the dilution factors for each sample, which range from 1 to 24.

Background mixing ratios are averaged over a single WAS sample collected east of the plume (orange star in Fig. 1). We also explored using observations upwind, downwind, or west of the plume for background estimation, but these samples contain stronger fire influence than the eastern sample based on the conserved fire tracers HCN and CH_3CN . These alternative background samples also contain higher O_3 (60–80 ppbv vs. 50 ppbv), leading to smaller or negative O_3 NEMRs and significantly poorer agreement with the model. The influence of background selection on NEMRs depends on the relative magnitude of background and in-plume mixing ratios, which varies with chemical species and age. Employing a constant background introduces additional uncertainty in observed NEMRs. Use of the same backgrounds in model simulations, however, reduces the impact of such uncertainties with regard to model–measurement comparisons.

2.2 Trajectory analysis

Air mass trajectories provide an estimate of smoke age and inputs for the puff model described below. Trajectories are computed with the Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model (Stein et al., 2015) interfaced with custom MATLAB software for input and output handling (<https://github.com/AirChem/HYSPLITcontrol>, last access: 1 November 2021). Trajectories are initialized at the midpoint of each WAS sample and run backward in time for 48 h. Outputs include both position and meteorology (temperature, pressure, relative humidity, solar zenith angle (SZA), and boundary layer depth). To build statistics, we utilize archive meteorological fields from the North American Mesoscale forecast system (NAM; 12 km; 1 h) and North American Regional Reanalysis (NARR; 32 km, 3 h) datasets (<https://ready.arl.noaa.gov/archives.php>, last access: 24 March 2020). Trajectories are executed as meteorological ensembles with the HYSPLIT default settings (27 members; 1 grid point horizontal shift; 0.01σ unit vertical shift), giving 54 trajectories per initialization. Next, we define a geographic box for the Rim Fire based on satellite imagery and fire counts (Fig. 1). Trajectories are filtered to exclude those not passing through this box. Filtered trajectories are spatially averaged using a geometric median (Zhong, 2021), resulting in one median trajectory for each observation (Fig. 1; inset). Meteorological quantities are averaged via the arithmetic mean.

We define Lagrangian smoke age from the time when an averaged trajectory last intersected the Rim Fire box out to

the downwind time of sampling. The standard deviation of smoke age from individual trajectories is typically $\sim 9\%$ of the mean for each ensemble, and we take this as a 1σ precision estimate. Smoke at our nominal starting point (the northern end of the box) is actually a mixture of ages. Based on observed wind speed and modeled trajectories near the fire, we estimate a transit time of ~ 1 h for emissions from the southernmost fire front to reach the northern end of the box. We take half of this value as an approximation for variability in actual smoke age. The total estimated uncertainty in average smoke age is then $9\% + 0.5$ h.

2.3 Puff model

The simulation of any fire plume is challenging due to high concentrations, strong dilution, aerosol radiative perturbations, and other factors. SEAC⁴RS did not sample the core of the Rim Fire plume, and smoke ages of 0–12 h were probed over a single hour of flight. Thus, if we wish to compare with observations, it is not adequate to represent the Rim Fire as a single Lagrangian plume. Detailed fire plume models have improved in recent years (Lonsdale et al., 2020), but observational constraints are limited compared to the complexity of such a model. The goal of our simulation is to obtain a meaningful comparison against observations without over-elaboration (Box, 1976).

In our model framework, the plume is approximated as a series of 0-D puffs. The puff model is developed within the Framework for 0-D Atmospheric Modeling (F0AMv4.2.1; available at <https://github.com/AirChem/F0AM/>, last access: 23 January 2020; Wolfe et al., 2016). One puff is simulated for each WAS sample/trajectory pair shown in Fig. 1. Each puff evolves in real time along the average trajectory, with meteorological constraints updated every 10 min. For each puff, along-trajectory pressure, temperature, relative humidity, and solar zenith angle are constrained with averaged trajectory output. Trajectory meteorology is rescaled by multiplicative factors (typically within a few percent of unity) based on the ratio of observed-to-trajectory values at trajectory endpoints. Photolysis frequencies are semi-constrained to observations using a two-part scaling that helps account for smoke radiative perturbations (Appendix A). Variations in scaling factors suggest stronger attenuation in the UV than the visible (compare $J(O^1D)$ and $J(NO_2)$ in Fig. A1b), consistent with other reports (Baylon et al., 2018). Chemical concentrations from the endpoint of each puff are extracted for comparison with observations.

Initial concentrations are the same for all puffs. These are estimated by combining Rim Fire emission ratios (ERs) from Liu et al. (2017), with the excess CO mixing ratio from the first sample of the long axis leg. Normalized excess mixing ratios for the near-source sample are generally within $\pm 50\%$ of the ERs reported by Liu et al. (2017) for the Rim Fire (Fig. S3). The Liu et al. (2017) ERs incorporate multiple near-source intercepts and are more repre-

sentative of average fire conditions. Actual ERs likely vary among the plume samples. Older samples represent fire emissions from earlier in the day, and we might expect these samples to show an increased signature of smoldering relative to flaming due to typical wildfire diurnal progression (Wiggins et al., 2020). Observations, however, do not conclusively indicate a time-dependent trend in ERs. MCE generally declines with age (Fig. S4a), consistent with a shift from smoldering to flaming over time, but frequent deviation from the expected wildfire value range of 0.8–1.0 (Akagi et al., 2011) suggests non-emission influence (e.g., background CO₂ variability) that degrades this metric as a combustion phase tracer at later ages. NEMRs for the conserved fire tracers HCN and CH₃CN exhibit some variability (standard deviation / mean = 10–15%) but no trend (Fig. S4b), suggesting no systematic change in fire-averaged ERs (Roberts et al., 2020). Conversely, the trend in total observed NO_y may indicate time-varying emissions (Sects. 3.1.4 and 4.2). Given these ambiguities, constant initial concentrations are a reasonable assumption.

Dilution is treated in analogy with Gaussian plume dispersion as follows (Alvarado et al., 2015):

$$\left(\frac{\partial X}{\partial t}\right)_{\text{dil}} = \frac{-1}{\tau_g + 2t} (X(t) - X_b). \quad (2)$$

Background concentrations (X_b) are the same as those used for dilution normalization in Eq. (1). The Gaussian timescale, τ_g , is constant for each puff and calculated using the analytical solution of the integral of Eq. (2) with CO concentrations at start and end points. The Gaussian timescale varies from 28 to 760 s for individual puffs (Fig. S5). Such variability is not surprising given the horizontal extent of the fire and differences among trajectories for each puff.

Model chemistry utilizes the Master Chemical Mechanism (MCMv3.3.1; Jenkin et al., 2015, 1997; Saunders et al., 2003) with modifications. Additional reactions include the photolysis of pernitric acid (Atkinson et al., 2004), reaction of methyl peroxy radical with OH (Assaf et al., 2016; Caravan et al., 2018), reaction of hydroxymethyl hydrogen peroxide (HMHP) with OH (Allen et al., 2018), and oxidation of propadiene (C₃H₄). For the latter, we use the OH reaction rate coefficient of Atkinson and Arey (2003) rather than the 1.8 times slower rate coefficient of Daranlot et al. (2012), owing to the similar observed decay rates of propadiene and ethene. Subsequent propadiene chemistry follows the mechanisms of Daranlot et al. (2012) and Xu et al. (2019). We also update rate coefficients for reaction of peroxyacetic acid with OH (Berasategui et al., 2020) and peroxyacyl radicals with HO₂ (Jenkin et al., 2019), which are slower/faster than MCM default values by factors of 123/1.33, respectively. The oxidation of some additional biomass burning VOC (furans, syringol, and guaiacol) is incorporated using an MCM extension developed following recent laboratory and field studies (Coggon et al., 2019; Decker et al., 2019, 2021a; Robinson et al., 2021).

There are multiple potential error sources in the puff model, and many are not easily quantified. We assume constant initial concentrations, but the smoke is a heterogeneous mixture of multiple ages and burning phases. Parameterizations for photolysis and dilution make assumptions about the history of each puff based on the observed evolution along the flight path. Heterogeneous chemistry is not explicitly included. Despite all these issues, results will illustrate that the puff model is a reasonable approximation and a useful test bed for probing plume chemistry. Measurement accuracy (Table S1) is typically the dominant uncertainty in observations at high signal-to-noise ratios (rather than precision); thus, we use this to define the uncertainty for model–measurement comparisons.

2.4 Model scenarios

Simulations systematically characterize the effects of varying emissions and chemistry (Table 1). In the base simulation (M0), initial species are limited to observations. This includes three species that are not in the MCM, namely furan, HMHP, and propadiene. Additional simulations incorporate unmeasured reactive VOC and HONO sources, as detailed below.

2.4.1 Addition of unmeasured VOC

Simulation M1 incorporates unmeasured VOC using the fire laboratory emissions data of Koss et al. (2018), which includes over 500 compounds and 20 western USA fuel types. We restrict this dataset to 152 compounds with specific molecular assignments and estimated OH reaction rate coefficients (Table S5 of Koss et al., 2018). Incorporating these data require (1) estimation of initial VOC concentrations and (2) allocation of these VOCs to model species. For the first step, we create a composite ER profile for the Rim Fire by comparing the ERs of the following 11 species reported by both Liu et al. (2017) and Koss et al. (2018): acetylene, ethene, propene, methanol, formaldehyde, acetaldehyde, furan, benzene, toluene, HCN, and CH₃CN. Specifically, we optimize fractional fuel contributions by minimizing the sum square relative error of log-transformed ERs between Liu et al. (2017) and the composite profile. Estimated fuel composition is sensitive to which VOCs are included in the optimization, as ER profiles are highly correlated among different fuels. For the same reason, model results are not especially sensitive to the choice of fuel composition. Combining composite ERs with observed CO in the first plume sample gives initial mixing ratios. We assume zero background for all unmeasured VOCs. ERs for acrolein and biacetyl are reduced by factors of 2.3 and 10, respectively, due to known calibration issues (Sect. S1).

Unmeasured VOCs are assigned to model species via one of two methods. A total of 51 species appear in the MCM or the extended NOAA biomass burning mechanism and

are thus accounted for explicitly. The remaining 101 compounds lack direct MCM analogues. These VOCs are allocated to MCM proxies based on OH reaction rate coefficients (k_{OH}) and molecular formulae. For each VOC, we first identify MCM species that are within some threshold (nominally 20 %) of the VOCs estimated k_{OH} . We then attempt to filter the MCM species list to include only those containing a similar number of carbon and oxygen atoms (within ± 1 the number of each atom). Specific functional groups are not considered. If the molecular formulae criterion is too restrictive (i.e., no species are identified), we only use the k_{OH} criterion. Table S2 lists the MCM assignments and ERs for all unmeasured VOCs. Figure S6 compares bulk chemical metrics between the non-MCM species of Koss et al. (2018) and assigned MCM proxies. Overall, proxies reproduce the distribution of OH reactivity (total 47 s^{-1}) and carbon content (390 ppbv C) and are biased high with respect to oxygen content and molecular weight. This is not surprising, as most VOCs contained in the MCM are multi-generation oxidation products.

2.4.2 Addition of HONO

HONO was not measured during SEAC⁴RS. Several sets of sensitivity simulations explore the impacts of primary (emitted) and secondary HONO. All of these simulations include the same initial unmeasured VOC as simulation M1. Simulations M2a, b, and c incorporate primary HONO at initial mixing ratios of 5, 15, and 25 ppbv, respectively. The upper end of this range is based on recent work reporting an average $\Delta\text{HONO} / \Delta\text{NO}_x$ emission ratio of $0.7 \pm 0.3 \text{ ppbv ppbv}^{-1}$ and an average $\Delta\text{HONO} / \Delta\text{CO}$ emission ratio of $5.3 \pm 5.2 \text{ pptv ppbv}^{-1}$ (where pptv is parts per trillion by volume) for western USA wildfires (Peng et al., 2020).

Simulations M3a, b, and c incorporate photolysis of particulate nitrate ($p\text{NO}_3^-$) as follows:

The photolysis frequency for reaction R1 is calculated as $286 \cdot J(\text{HNO}_3)$, following Ye et al. (2017, 2018). The mechanism for this reaction is not well understood (Baergen and Donaldson, 2013), and the efficacy of $p\text{NO}_3^-$ photolysis likely depends on aerosol composition (Ma et al., 2021). Other studies have estimated photolysis frequencies an order of magnitude or more lower in non-biomass burning environments (Romer et al., 2018; Shi et al., 2021). Particulate nitrate concentrations are constrained by aerosol mass spectrometer (AMS) observations (Fig. S7a). Comparison with other aerosol composition observations suggests minor $p\text{NO}_3^-$ contained in coarse-mode aerosol, which is excluded by the AMS (Fig. S8). It is not possible to partition AMS $p\text{NO}_3^-$ between organic and inorganic forms for SEAC⁴RS (Ulbrich et al., 2009; Day et al., 2022); however, the nature of particulate nitrate participating in Reaction (R1) is also

Table 1. Summary of model simulations. Note: ppbv is parts per billion by volume.

Simulation	Description
M0	Base simulation using only measured VOC
M1	M0 + unmeasured VOC
M2a,b,c	M1 + primary HONO (5, 15, and 25 ppbv)
M3a,b,c	M1 + secondary HONO via $p\text{NO}_3^-$ photolysis ($J(p\text{NO}_3^-)$ scaling factors of 0.5, 1, 2)
M4a,b	M1 + secondary HONO via NO_2 + aerosol ($\gamma(\text{NO}_2)$ scaling factors of 1, 1000)

unclear. For all puffs, $p\text{NO}_3^-$ is initialized with the observed concentration in the near-source sample. The model treats $p\text{NO}_3^-$ as non-reactive (no chemical production or loss), but it dilutes with a puff-dependent background concentration, chosen such that concentrations match observations at the start and end of each puff. This is a workaround to ensure the model carries reasonable $p\text{NO}_3^-$ concentrations throughout the simulation in the absence of explicit model aerosol chemistry. Simulations M3a, b, and c scale the nominal rate of Reaction (R1) by factors of 0.5, 1, and 2, respectively.

Simulations M4a and b incorporate reaction of NO_2 on aerosol surfaces as follows:

$$k_a = 0.25 v_{\text{NO}_2} S_a \gamma. \quad (3)$$

Here, k_a is the first-order rate coefficient, v_{NO_2} is the mean molecular speed of NO_2 , S_a is particle surface area density, and γ is the reactive uptake coefficient. We assume that gas diffusion is not a limiting factor for small values of γ (10^{-3} to 10^{-6}). For S_a , we use laser aerosol spectrometer observations (Yu et al., 2016) scaled up by a factor of 1.7 to account for calibration bias (Fig. S8) and linearly interpolated over plume age. Values of S_a range from 800 to $6600 \mu\text{m}^2 \text{cm}^{-3}$ (Fig. S7b). In the following, the parameterization of γ follows a laboratory-derived relationship with solar radiation (Stemmler et al., 2006; Zhang et al., 2019):

$$\gamma = \begin{cases} \alpha J_{\text{NO}_2}, & \text{Rad} \leq 400 \text{ W m}^{-2} \\ \alpha J_{\text{NO}_2} (\text{Rad}/400)^2, & \text{Rad} > 400 \text{ W m}^{-2} \\ 10^{-6}, & \text{minimum} \end{cases}. \quad (4)$$

Here, J_{NO_2} is the NO_2 photolysis frequency derived from the model, $\alpha = 2.5 \times 10^{-4}$ is a scaling factor, and Rad is total solar irradiance. The latter is estimated using trajectory-dependent SZA and the linear relationship between SZA and observed solar irradiance (Fig. S9). Some minor systematic bias in Rad may result from extrapolation of this relationship. The minimum value of γ follows Aumont et al. (2003). Figure S7c–d show calculated γ and k_a at the end point of each puff. The uptake coefficient ranges from $4\text{--}11 \times 10^{-6}$, while k_a ranges from $0.3\text{--}4.9 \times 10^{-6} \text{ s}^{-1}$. Note that k_a varies along the trajectory for each puff due to changes in radiation and S_a . Simulation M4a uses this default parameterization, while, in simulation M4b, k_a is multiplied by a fac-

tor of 1000. This range spans observed NO_2 uptake on humic acid ($\gamma = 2\text{--}8 \times 10^{-5}$; Stemmler et al., 2006) and soot ($\gamma = 3.7\text{--}11 \times 10^{-3}$; Ammann et al., 1998) surfaces. We do not consider ground surface HONO sources (Chai et al., 2021), as observations are limited to the free troposphere and uppermost mixed layer.

3 Results

3.1 Observations and base simulation

We first examine the evolution of observed trace gases in the Rim Fire plume. Observations illustrate several general features, including (1) rapid oxidation of primary emissions and production of secondary species in the first 2 h of aging, (2) mixing with biogenic emissions around an age of 2–3 h, and (3) a transition in some species associated with a decrease in sampling altitude around an age of 6 h (Fig. S1). The following sections survey age-dependent trends in primary VOC, peroxides, oxygenated VOC, reactive nitrogen, and ozone. We compare the representation of this chemistry with MCMv3.3.1 and available constraints to base simulation output (M0) benchmarks.

3.1.1 VOC

The downwind evolution of primary VOC illustrates the differing effects of emissions, dilution, and oxidation. We group VOC into the following four categories: long-lived alkanes, aromatics/intermediate-lived alkenes, short-lived alkenes, and biogenic terpenes. Groups reflect photochemical lifetimes and similarities in model normalized mean bias (NMB). Figure 2a–d show an example from each category, Fig. S10 shows the time series of all observed VOC, and Fig. S11 shows the NMB for each VOC calculated over the full simulation.

Long-lived alkanes such as ethane, propane, and butanes do not decay monotonically with plume age (Figs. 2a and S10a–d). NEMRs for these gases peak downwind of the Rim Fire; for example, the highest propane NEMR occurs at an age of 4 h and is 50 % higher than the initial value. All model simulations exhibit negative NMB of -26% or less for these gases (Fig. S11). With lifetimes of days or more against OH oxidation, these gases are relatively sensitive to variability in background levels and regional emissions (e.g., urban

and oil/natural gas activities). For example, at an age of 4 h the ethane enhancement is four times its background value, whereas the ethene enhancement is a factor of 70. Variability in fire emissions is a less likely explanation for model–measurement mismatch. Reconciliation with the observed increase in NEMRs at an age of 2 h would require VOC-to-CO emission ratio increases of 50 %–100 %, and we would expect similar changes in other VOC emission ratios (Liu et al., 2017; Permar et al., 2021) that are not observed. These VOCs are minor contributors to plume photochemistry; however, this comparison underscores the challenge of accounting for background variability in Lagrangian or pseudo-Lagrangian simulations.

The second group, including most aromatics (benzene, toluene, ethyl benzene, and xylenes) and several alkenes (ethene and propadiene), exhibits stronger NEMR decays with age (Figs. 2b and S10e–k). Photochemical lifetimes for these gases range from 11–48 h (except for benzene, with a lifetime of 4–10 d); thus, we expect both emissions and chemistry to influence NEMR variability. Similar to alkanes, longer-lived aromatic NEMRs peak at 2–6 h of age. Xylenes, ethene and propadiene exhibit a more monotonic decay. The base model NMB is below 8 % for the latter three compounds.

Oxidation controls the trend of short-lived alkenes, including propene, butenes, butadiene, pent-1-ene, and furan (Figs. 2c and S10l–s). These gases have near-zero background mixing ratios and react primarily with OH. Loss via O₃ reaction is <15 % of the total loss rate, and nitrate radical reaction is negligible within sampled air masses. NEMRs decay rapidly, and the most reactive gases fall below measurement detection limits at later ages. The base model simulation exaggerates this decay, resulting in negative NMB as large as –233 % for furan.

Terpenes (isoprene and α/β -pinene) are also highly reactive, and NEMRs generally decay rapidly (Figs. 2d and S10t, u). Around an age of 2 h, however, NEMRs increase beyond those in the near-source sample. A similar pattern appears in the isoprene oxidation products methyl vinyl ketone (MVK) and methacrolein (MACR; Fig. S12d). Furthermore, this particular sample is uncharacteristically dilute relative to the Lagrangian age (Fig. S2). This evidence suggests that local biogenic emissions mixed with the Rim Fire smoke samples at Lagrangian ages of 2–4 h.

3.1.2 HO_x and peroxides

The SEAC⁴RS DC-8 payload did not include observations of HO_x (= OH + HO₂). The loss and production of other compounds, however, indirectly constrains HO_x abundance. The decay rate of short-lived alkenes provides a benchmark for OH, while peroxide production is an indicator for HO₂ and, to some extent, organic peroxy radicals (RO₂).

As discussed above, short-lived alkene NEMRs decay faster than observed NEMRs in the base simulation, especially in the first few hours. The discrepancy between modeled and observed short-lived alkenes suggests an over-prediction of OH in the young plume. Base simulation OH starts at $4.9 \times 10^6 \text{ cm}^{-3}$ and declines to $\sim 1.2 \times 10^6 \text{ cm}^{-3}$ after ~ 4 h (Fig. S13a).

Self-reaction of HO₂ produces hydrogen peroxide (H₂O₂), and reaction of HO₂ with peroxyacetyl radical (PA) produces peroxyacetic acid (PAA). NEMRs for both peroxides start low and increase with plume age (Fig. 2e, f). Initial mixing ratios are near background levels, which is at odds with a previous study suggesting significant primary emissions (Lee et al., 1997). The base simulation exhibits an upward trend but with a slower growth rate, especially over the first 4 h. Model H₂O₂ NEMRs skirt the lower edge of measurement accuracy, while PAA agreement generally improves with age. This comparison suggests under-prediction of HO₂ and possibly RO₂ at early ages. Base model HO₂ peaks at ~ 85 pptv and declines to values as low as 23 pptv (Fig. S13b).

3.1.3 Oxygenated VOC

Formaldehyde (HCHO), an oxidation product of numerous VOC, serves as a top-down constraint on in-plume VOC processing. The observed HCHO NEMR decreases by a factor of 3 in the first 5 h before leveling out at later ages (Fig. 2g). This behavior is consistent with loss of primary emissions alongside secondary production (Liao et al., 2021). The HCHO lifetime due to photolysis and OH oxidation is ~ 3.5 h at the time of sampling, but accumulation of multi-generation oxidation products may sustain downwind HCHO production (Alvarado et al., 2020). The rise in the HCHO NEMR between 5 and 7 h coincides with descent to a lower sampling altitude (Fig. S1). The base simulation follows observations early on but underestimates NEMRs later.

The acetaldehyde (CH₃CHO) NEMR decay exhibits a more constant slope (Fig. 2h). The small post-emission peak in the acetaldehyde NEMR at an age of 2 h coincides with the aforementioned sharper peaks in biogenic markers and enhancements in long-lived alkanes, which may indicate influence from non-fire surface emissions. Base model NEMRs initially decay more rapidly than observed, but the slope matches observations after the first few hours. This discrepancy is consistent with over-prediction of OH in the young plume, as OH oxidation accounts for 80 % of acetaldehyde loss. Conversely, OH only accounts for 15 %–50 % of HCHO loss (photolysis is the remainder). Thus, as will be evident in sensitivity simulations discussed later, HCHO and CH₃CHO exhibit opposite responses to varying OH.

Section S2 and Fig. S12 present several other oxygenated VOC (oVOC) observations, including methanol, acetone + propanal, hydroxyacetone, and MVK + MACR.

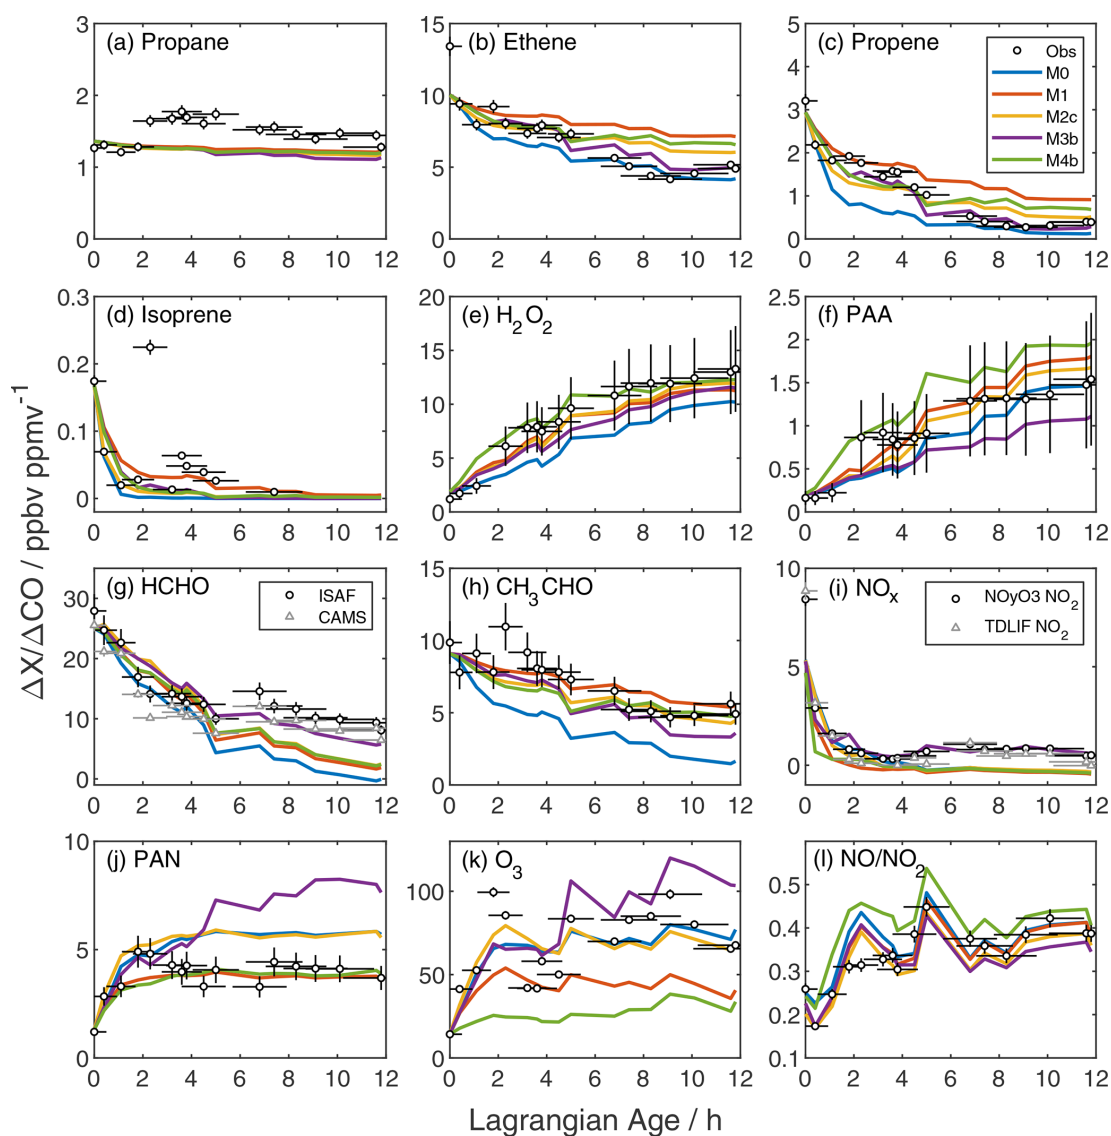

Figure 2. Age evolution of NEMRs for reactive gases (a–k) and the NO / NO₂ ratio (l). Black circles are observations with their corresponding uncertainty due to measurement accuracy and age. Colored lines are the model output from the base simulation (M0; blue), addition of unmeasured VOC (M1; red), and addition of unmeasured VOC plus initial HONO (M2c; yellow), *p*NO₃[−] photolysis (M3b; purple), or NO₂ heterogeneous uptake (M4b; green). In panels (g) and (i), circles and triangles represent two independent measurements of HCHO and NO₂, respectively (Table S1). NO and NO₂ observations in panel (l) are from the NO_yO₃ instrument.

3.1.4 Reactive nitrogen

Major wildfire reactive nitrogen emissions include NO_x, HONO, and NH₃ (Lindaas et al., 2020; Roberts et al., 2020). Observations of HONO and NH₃ are not available for SEAC⁴RS, so here we focus on NO_x and observed reservoir species including peroxyacyl nitrates, alkyl nitrates, and nitric acid.

The base simulation reasonably reproduces the initial loss of NO_x but does not capture later behavior (Fig. 2i). In the first few hours, the NO_x NEMR decays with an *e*-folding timescale of 20–40 min. After reaching a minimum

at ~ 3.6 h, the NO_x NEMR rises to a sustained enhancement at ~ 10 % of the initial value. An additional NO_x source of 200 pptv h^{−1} is required to close the NO_x budget in the period between 6 and 12 h. This discrepancy is explored further in Sect. 3.3.

Peroxyacetyl nitrate (PAN) typically comprises the majority of total peroxy nitrates (Wooldridge et al., 2010) and is produced via the reversible reaction of NO₂ with PA. The PAN NEMR rises rapidly in the first 2 h before stabilizing (Fig. 2j), comparable to previous observations (Alvarado et al., 2010, 2015). The base simulation captures the early rise in PAN but overshoots the asymptote by ~ 20 %. Sec-

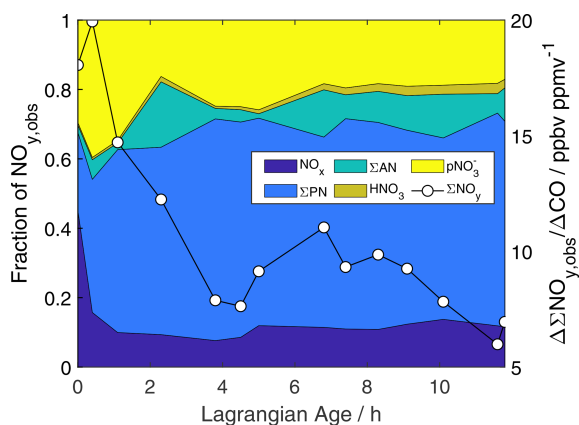

Figure 3. Age evolution of observed NO_y speciation (solid colors; left axis) and the $\Sigma\text{NO}_{y,\text{obs}}$ NEMR (white circles/line; right axis). $\Sigma\text{NO}_{y,\text{obs}}$ is the bottom-up sum of observed NO_y . ΣPN represents tunable diode laser-induced fluorescence (TDLIF) observations.

tion S3 and Figs. S14–S15 compare the model output to measurements of other speciated peroxy nitrates, total peroxy nitrates, and alkyl nitrates, which show varying levels of model–measurement agreement.

Reaction of OH with NO_2 primarily forms nitric acid (HNO_3). The observed HNO_3 NEMR is negative and trends downward with age, indicating that in-plume HNO_3 is below background levels (Fig. S15c). Excess ammonia/ammonium (Perring et al., 2017) likely drives rapid formation of particulate ammonium nitrate (Lindaas et al., 2021). The puff model lacks aerosol chemistry and thus predicts net growth of the HNO_3 NEMR. The difference between the base model and observed HNO_3 NEMR implies an effective HNO_3 lifetime of less than 1 h within the plume.

Figure 3 shows the evolution of the sum of observed NO_y . We refer to this quantity as $\Sigma\text{NO}_{y,\text{obs}}$ to acknowledge missing observations of some NO_y species such as HONO, HO_2NO_2 , nitroaromatics, and possibly other organonitrates. Peroxyacyl nitrates (PNs) comprise 20 % of $\text{NO}_{y,\text{obs}}$ within the first sample, consistent with a mixture of smoke ages. After the first hour, PNs comprise more than half of $\Sigma\text{NO}_{y,\text{obs}}$, $p\text{NO}_3^-$ comprises another 20 %–30 %, and NO_x and alkyl nitrates contribute 10 %–15 % each. The $\Sigma\text{NO}_{y,\text{obs}}$ NEMR decreases from as high as $19.9 \text{ ppbv ppmv}^{-1}$ (where ppmv is parts per million by volume) to as little as 6 ppbv ppmv^{-1} over 12 h of aging. Underlying this trend is a rapid NO_x decay, a step change in $p\text{NO}_3^-$ at an age of 2 h, and a gradual decline in ΣPN (Fig. S16). Figure S17 compares observed gas-phase NO_y ($\Sigma\text{NO}_{y,\text{gas}}$, which excludes $p\text{NO}_3^-$) with the model-equivalent sum. The observed gas-phase sum decreases with age from 12.5 to $4.4 \text{ ppbv ppmv}^{-1}$ and is $\sim 7 \text{ ppbv ppmv}^{-1}$ throughout simulation M0. The causes and consequences of this discrepancy are further discussed in Sect. 4.1.

3.1.5 Ozone

The observed O_3 NEMR grows rapidly within the first few hours before slowing down (Fig. 2k). The peak value at 2 h coincides with the aforementioned peak in biogenic VOC. The base simulation reproduces the general trend of the observed O_3 NEMR time profile but misses the maximum and under-predicts after 5 h. Significant point-to-point variability in the observed O_3 NEMR mostly reflects variability in the CO excess mixing ratio rather than O_3 itself, as O_3 is relatively close to its background value. Absolute O_3 reaches a peak of 130 ppbv within the first hour before diluting rapidly to 65–75 ppbv, remaining above the background estimate of 50 ppbv (Fig. S18). Mean absolute bias for base simulation O_3 is -3.2 ppbv averaged over all observations and $+0.5 \text{ ppbv}$ for ages greater than 2 h.

The ratio of NO to NO_2 relates closely to radical turnover and O_3 production. In the absence of strong NO_x sources or sinks, photolysis of NO_2 and oxidation of NO establishes a photostationary state that controls this ratio, as follows:

$$\frac{[\text{NO}]}{[\text{NO}_2]} = \frac{J_{\text{NO}_2}}{k_{\text{NO}+\text{O}_3}[\text{O}_3] + k_{\text{NO}+\text{HO}_2}[\text{HO}_2] + \sum k_{\text{NO}+\text{RO}_2}[\text{RO}_2]} \quad (5)$$

Here, J_{NO_2} is the NO_2 photolysis frequency, and k_{x+y} are reaction rate coefficients. The observed NO / NO_2 ratio doubles over the course of 12 h (Fig. 2l), consistent with the decline of peroxy radicals and ozone mixing ratios. $J(\text{NO}_2)$ does not exhibit a clear trend over this period (Fig. A1). The base simulation over-predicts this ratio in the first few hours and agrees within uncertainties afterward. Disagreement at young ages is consistent with insufficient conversion of NO to NO_2 , possibly due to insufficient ozone and/or peroxy radicals.

3.2 Accounting for unmeasured VOC

Differences between observations and the base simulation are consistent with missing reactive VOC in the model. The decay of reactive alkenes is faster than observed, suggesting that model OH is too high. Production of peroxides and HCHO is too slow, indicating missing sources of peroxy radicals and organic carbon. Simulation M1 approximates the effects of unmeasured VOC, which is incorporated following the procedures outlined in Sect. 2.4.1.

Total OH reactivity – the inverse of the OH lifetime – increases significantly upon addition of unmeasured VOC (Fig. 4a). Initial OH reactivity grows from 77 to 182 s^{-1} . The top five components of OH reactivity in the observations and simulation M0 are HCHO, CO, CH_3CHO , furan, and propene (Fig. 4c). Species included in simulation M0 comprise $\sim 45 \%$ of the OH reactivity in simulation M1. The top five additional contributors in simulation M1 are aromatics, consistent with Coggon et al. (2019). Enhancements persist as the plume ages, with OH reactivities of 7 s^{-1} (M1) ver-

sus 3 s^{-1} (M0) at an age of 12 h. After 12 h, 32 % of the M1-simulated OH reactivity is comprised of over 2100 species that are, individually, not very abundant (Fig. 4c; gray area). Comparing M0 and M1 suggests that 85 % of this secondary reactivity (1.8 s^{-1}) is due to the oxidation of unmeasured VOC.

Normalizing for dilution reveals a more modest decline in OH reactivity due to photochemistry alone (Fig. 4b). Normalized excess OH reactivity declines by 61 % and 45 % for M0 and M1, respectively. The relatively slower decline in M1 reflects less OH in this simulation. Modeled declines in OH reactivity over 12 h of aging imply pseudo-first-order lifetimes of 12.7 and 21.4 h for OH reactivity in simulations M0 and M1, respectively. OH reactivity estimates from the model may be an upper limit, as some reactive carbon will partition to the aerosol phase (Palm et al., 2020).

Additional VOC reactivity markedly alters downwind chemistry. OH decreases to $5 \times 10^5 \text{ cm}^{-3}$ for most of the simulation (Fig. S13a), reducing the decay of reactive alkenes to a shallower slope than observed (Fig. 2b–d). Maximum HO₂ increases by 35 % (Fig. S13b), and H₂O₂ agrees better with observations (Fig. 2e). PAA increases due to the enhanced production of HO₂ and PA (Fig. 2f). The peroxyacetyl radical is also a PAN precursor, but PAN actually decreases in simulation M1 due to lower NO₂ (Fig. 2j) and competing formation of larger peroxy nitrates (Figs. S14, S15). Rapid sequestration of NO_x also suppresses ozone formation in the young plume (Fig. 2k). HCHO and CH₃CHO increase (Fig. 2g–h), but the model still under-predicts HCHO at later ages.

3.3 Accounting for primary and secondary HONO

The contrast of observations and simulation M1 in Fig. 2 implies insufficient OH and NO_x. The decay of short-lived alkenes is now slower than observed owing to the large increase in OH reactivity, while the decay of NO_x is faster than observed due to rapid peroxy nitrate formation. Faster NO_x sequestration also reduces O₃ production.

Potential explanations for model–measurement discrepancies in NO_x include NO₂ measurement artifacts, emissions variability, unaccounted-for recycling via NO_x reservoirs, and missing NO_x sources. NO₂ measurement artifacts are unlikely to play a significant role, given the excellent correlation between two independent NO₂ measurements and the magnitude of model–measurement disagreement (Sect. S3). Doubling initial NO_x has a minor effect on the simulated NO_x NEMR after ~ 5 h (Fig. S19), and total observed NO_y decreases with Lagrangian age (Fig. 3); thus, NO_x emissions variability also cannot explain this difference. Recycling via decomposition or oxidation of NO_x reservoirs, such as organic nitrates, should be adequately captured by simulation M1 as the NEMRs of total peroxy nitrates, and alkyl nitrates are simulated well (Figs. S14 and S15). We lack observations of HO₂NO₂ or CH₃O₂NO₂, but lifetimes for these gases are a few minutes for model conditions and modeled mixing ra-

tios are less than 10 pptv after 5 h. Nitroaromatic photolysis may generate HONO (Sangwan and Zhu, 2016), but these compounds do not build up to sufficient levels to act as a major NO_x source in the model. Therefore, a missing NO_x source is the most likely explanation.

Previous work has demonstrated the important role of HONO in smoke plume chemistry (Alvarado et al., 2015; Alvarado and Prinn, 2009; Peng et al., 2020; Theys et al., 2020). Direct HONO emissions amplify radical production in the nascent plume, while secondary HONO formation may sustain oxidation as the plume ages. As discussed in Sect. 2.4.1 and summarized in Table 1, we implemented both primary emissions (simulations M2a, b, c) and secondary production via $p\text{NO}_3^-$ photolysis (M3a, b, c) or a heterogeneous NO₂ reaction (M4a, b). Figure S20 shows the absolute HONO mixing ratio, HONO NEMR, and HONO / NO₂ ratio for several representative simulations. The HONO photolysis lifetime, based on observed photolysis frequencies, is 10–20 min. HONO mixing ratios in simulations with secondary production (M3b and M4b) are tens of pptv after a few hours. Initial HONO NEMRs and HONO / NO₂ ratios fall within the range observed in other fire plumes (Peng et al., 2020; Theys et al., 2020). Most figures in the main text and the Supplement display results from simulations with high primary HONO (M2c), moderate $p\text{NO}_3^-$ photolysis (M3b), and fast NO₂ heterogeneous uptake (M4b), while Figs. S21–S23 show the full results for each sensitivity series.

Initial HONO stimulates chemistry in the first several hours. Simulation M2c starts with 25 ppbv of HONO, comparable to maximum levels observed in other western USA wildfires (Peng et al., 2020). The photolysis of HONO increases OH and NO production, leading to faster VOC decay and product formation (Figs. 2 and S11). Intensification is limited to the first few hours, and the decay of short-lived alkenes, like propene and butenes, is too slow at later ages (Fig. 2c). NO_x agreement also improves at early times, but under-prediction persists after 3 h of aging (Fig. 2i). PAN and O₃ profiles are close to those in the base simulation (Fig. 2j–k). Observed NO_y NEMRs are over-predicted (Fig. S17).

Photolysis of $p\text{NO}_3^-$ leads to more sustained impacts. Simulation M3b uses the literature-derived rate for reaction R1 (Ye et al., 2017). For this case, median OH increases by a factor of 3.5 relative to simulation M1 (Fig. S11), improving model agreement with short-lived VOC (Fig. 2b–c). HO₂ is mostly unchanged, reflecting a counterbalance of faster production via VOC oxidation and faster loss via reaction with NO. Unique to the mechanisms tested in this study, $p\text{NO}_3^-$ photolysis reproduces the enhancements in HCHO and NO_x NEMRs observed at later ages (Fig. 2g, i). The HONO NEMR at ages beyond 2 h also aligns with values observed in other wildfires (Fig. S20b). On the other hand, PAN and ozone are now over-predicted (Fig. 2j–k), as are ΣPN, some speciated PNs, and ΣNO_{y,obs} (Figs. S14, S15, S17). Halving the $p\text{NO}_3^-$ photolysis rate improves the agreement with PAN and O₃ at the expense of NO_x and HCHO (Fig. S22; compare

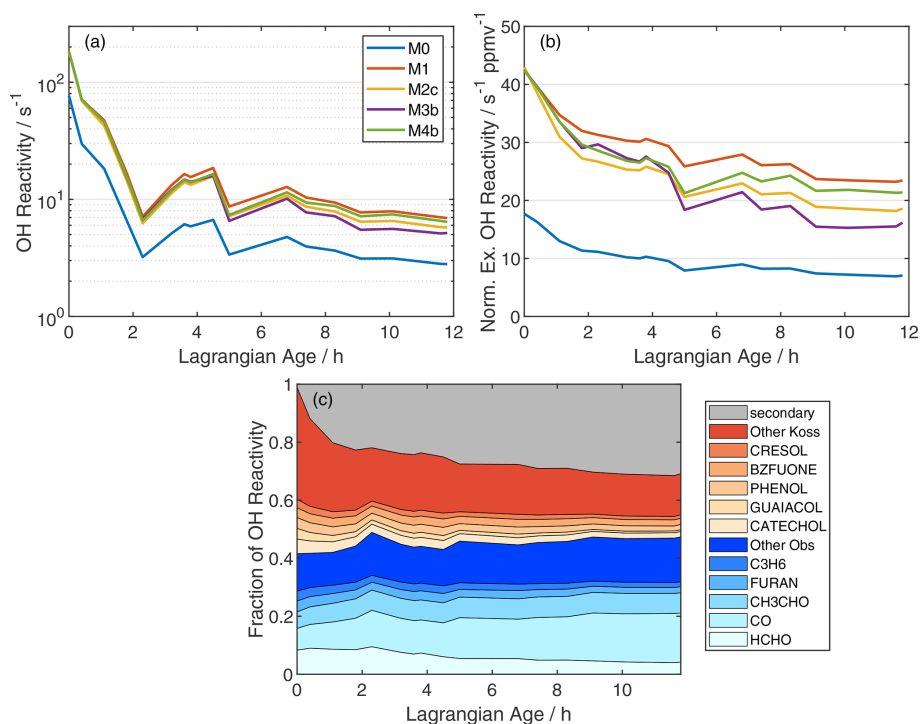

Figure 4. (a) Age evolution of total model OH reactivity, (b) normalized excess OH reactivity, and (c) fractional contributions of individual reactants to total OH reactivity in simulation M1. In panel (b), normalization is analogous to NEMR calculation (Eq. 1), and the OH reactivity background is 1.1 s^{-1} , based on summation over observed OH reactants in the background sample. In panel (c), blue shades denote measured compounds, red shades are species added from the Koss et al. (2018) inventory, and gray includes 2116 other MCM species reacting with OH.

simulations M3a and M3b). Over-prediction of PAN and its analogues in these simulations may reflect errors in the VOC distribution and/or chemical kinetics (Sect. 4.3). These simplified simulations also do not consider age-dependent variability in aerosol composition (e.g., organic versus inorganic $p\text{NO}_3^-$), which could influence the effective $p\text{NO}_3^-$ photolysis rate and product yields.

The supply of $p\text{NO}_3^-$ imposes a practical limit on the rate of HONO and NO_2 production via this process. Particulate nitrate production and loss is not rigorously modeled in our simulations, but we can estimate the magnitude of this limitation. A linear fit to the observed $p\text{NO}_3^-$ NEMR yields an e -folding timescale of 9.6 h, whereas the effective lifetime of $p\text{NO}_3^-$ with respect to photolysis in simulation M3b is $3.4 \pm 0.6 \text{ h}$ (mean and standard deviation, averaged over the endpoints of all puffs). Nitric acid and organic nitrate partitioning to particles may resupply some $p\text{NO}_3^-$ downwind; observations in other wildfire plumes show $p\text{NO}_3^-$ NEMRs increasing with age (Juncosa Calahorrano et al., 2020). Given the uncertainties regarding the fate of NO_y (Sect. 4.1), the observed $p\text{NO}_3^-$ lifetime is not a strong constraint on the potential chemical loss; however, $p\text{NO}_3^-$ photolysis rates are unlikely to be larger than those used in our study, and the comparison with observed gas-phase NO_y (Fig. S17) suggests they may be substantially slower.

HONO production via heterogeneous reaction of NO_2 generally degrades agreement with observations (Fig. S23). Results from simulation M4a are nearly identical to those from M1, while in simulation M4b ($\gamma \times 1000$) ozone and NO_x under-prediction worsens. Coupled with rapid HONO photolysis, this process effectively converts NO_2 to NO while generating OH. This acts as a non-photolytic NO_2 sink and increases the loss of O_3 to reaction with NO (reflected in the NO/NO_2 ratio), reducing net O_3 production. NO_2 conversion to HONO is nearly NO_x neutral, whereas $p\text{NO}_3^-$ photolysis is effectively a NO_x source (Fig. S17). This is also evident in the HONO/ NO_2 ratio, which ranges from 0.2 to 3.9 and exceeds the ratio for simulation M3b by a factor of 4 or more (Fig. S20c).

Additional reactive VOC and HONO chemistry can collectively improve the model–measurement agreement for most observed species, but the implementation of each process is not quantitatively independent. Model performance relative to observations inherently relies on a balance between oxidant sinks (VOC) and sources (HONO), both of which are uncertain. Section S4 describes extended simulations with the simultaneous tuning of initial unmeasured VOC mixing ratios, initial HONO mixing ratios, and $p\text{NO}_3^-$ photolysis rates. Results demonstrate that multiple combinations of these processes can reasonably reproduce the age

evolution of ozone and some other species. No combination of scaling factors, however, optimizes agreement among all observations.

4 Discussion

4.1 NO_y conservation

As noted in Sect. 3.1.4, the $\Sigma\text{NO}_{y,\text{obs}}$ NEMR declines by a factor of 3 over 12 h of aging. For a well-defined plume, total NO_y should be conserved (Juncosa Calahorrano et al., 2020). The Rim Fire plume is larger and more disperse than most previously studied wildfires, and SEAC⁴RS observations provide limited information regarding variability in emissions or background concentrations. Potential explanations for the apparent decline of the $\Sigma\text{NO}_{y,\text{obs}}$ NEMR in the Rim Fire plume include (1) conversion to unmeasured NO_y, (2) changing NO_x emission ratios, (3) unmeasured background variability, and (4) deposition. The last of these is unlikely, given that sampling occurred in the uppermost boundary layer and lower free troposphere.

Conversion of measured to unmeasured long-lived NO_y may provide a partial explanation. The SEAC⁴RS measurement suite includes many, but not all, classes of NO_y. More recent observations of smaller USA wildfires, using new measurement techniques that better speciate organic nitrogen, have shown conservation of the ΣNO_y NEMR at physical ages up to 5 h (Juncosa Calahorrano et al., 2020). Comparison to this more recent dataset suggests that unmeasured NO_y (such as complex organic nitrates) might account for 10 %–20 % of the $\Sigma\text{NO}_{y,\text{obs}}$ NEMR decrease in the Rim Fire plume. Photolysis of unmeasured HONO emissions could buffer this loss by generating NO_x on short timescales (Fig. S17).

Changing NO_x emission ratios are another possible explanation. As discussed in Sect. 2.3, older samples represent emissions from earlier in the day, when we might expect more smoldering combustion (Wiggins et al., 2020). Other evidence for the changing fire phase, including MCE and nitrile NEMRs (Fig. S4), is inconclusive. NO_x emission factors (g kg⁻¹ of fuel burned) can increase by a factor of 2 or more over the range of typical MCE values (Lindaas et al., 2020), and we might expect a similar trend in NO_x ERs. To illustrate potential impacts, we performed sensitivity tests on simulation M1 with initial NO_x multiplied by a factor of 0.5 or 2 (Fig. S24). This nearly spans the range of observed ΣNO_y . We have relatively more confidence in the NO_x ER at early ages (Liu et al., 2017), so we focus on the half-NO_x case that approaches $\Sigma\text{NO}_{y,\text{obs}}$ at later ages. Halving initial NO_x reduces model O₃ and PAN, increases VOC lifetimes (less OH), and increases peroxide production. Accounting for potential emission changes rigorously in the model would complicate analysis of HONO mechanisms. For example, adding HONO via initial conditions or *p*NO₃⁻ photolysis to increase radical production increases model NO_y, necessitating fur-

ther initial NO_x reduction to maintain agreement with observed NO_y. Heterogeneous conversion of NO₂ does not alter total NO_y, but it also does not amplify ozone. Because of these uncertainties, ΣNO_y is a weak constraint on HONO chemistry in this case study. Regional and global model simulations also utilize time-invariant emission factors, which likely impacts their representation of diurnal variability of biomass burning chemistry.

Variable background mixing ratios may also impact calculated NEMRs, especially at later ages. For reasons detailed in Sect. 2.1, we assume constant backgrounds. The $\Sigma\text{NO}_{y,\text{obs}}$ background is 0.7 ppbv. Assuming instead a background of 0 ppbv increases the $\Sigma\text{NO}_{y,\text{obs}}$ NEMR by a factor of 1.45 at the oldest ages, but this is an extreme lower limit and assumes constant background CO. We have more confidence in the background estimation at early ages, when dilution is strongest. Furthermore, the same background is used for both the modeled and observed NEMRs. Thus, variable backgrounds may have some influence on observed NO_y NEMRs but a lesser impact on model–measurement comparisons.

In summary, declining NO_x emission ratios are the most likely explanation for the age dependence of the $\Sigma\text{NO}_{y,\text{obs}}$ NEMR, but we cannot exclude the potential influence from unmeasured NO_y and changing backgrounds. These uncertainties were acknowledged at the outset of the model analysis, and this reinforces the need for caution when interpreting model–measurement agreement at later ages. Nonetheless, the comparison of different simulations can yield insight into the consequences of augmenting canonical chemistry with new species and reactions.

4.2 Radical production and fate

The inclusion of additional reactive VOC and HONO significantly accelerates radical throughput. Figure 5a–b summarize rates of key RO_x (OH + HO₂ + RO₂ + RO) production and loss pathways integrated over the first 2.3 h of plume aging, where NEMRs change most rapidly. Compared to the base simulation, total RO_x initiation and termination doubles in simulation M1 (VOC addition) and more than triples in M2c (initial HONO). As illustrated in Sect. 3, these changes influence the lifetime of reactive gases and the production of secondary compounds such as ozone, peroxides, organic nitrates, and oVOC. Comparison of O₃ NEMRs in Fig. 2k, however, also demonstrates simulation of an ozone profile that reasonably matches observations even with missing processes. Constraints on other aspects of the chemical system facilitate a holistic evaluation of additional chemistry.

Photolysis sources dominate radical initiation (Fig. 5a). Photolysis of O₃ to O¹D and H₂O₂ are each less than 2 % of total production in all simulations. In the base simulation, photolysis of HCHO and other oVOC comprises 75 % of the radical source. Enhanced reactive VOC in simulation M1 doubles the initiation rate, mainly via further oVOC photoly-

sis and alkene ozonolysis. The largest contributors in the former category are glyoxal (19 %) and methyl glyoxal (15 %). HONO photolysis in simulations M2–M4 further accelerates initiation. Simulation M2c (initial HONO) exhibits the most substantial increase in the plotted simulations, with HONO photolysis comprising 33 % of initiation.

The relative contribution of HONO is smaller here than in other recent studies (Peng et al., 2020; Robinson et al., 2021; Theys et al., 2020) for at least two reasons. First, we average over the first 2.3 h of aging based on observed rapid ozone production, while other studies may integrate over a shorter timescale when HONO is relatively more important. Second, incorporation of an extended VOC pool greatly enhances oVOC photolysis in our study. oVOC photolysis may be underestimated in previous radical production estimates. Peng et al. (2020) only account for HCHO and CH₃CHO, Theys et al. (2020) account for photolysis of 16 oVOC, and Robinson et al. (2021) do not incorporate VOC beyond those appearing in the MCM or the extended biomass burning mechanism. There is uncertainty in this contribution due to MCM mapping of VOC (Table S2; Fig. S6). Nonetheless, studies failing to account for all oVOC may under-predict radical initiation and over-estimate the relative importance of other radical sources. This may also be the case for urban environments (Qu et al., 2021).

Radical termination includes significant contributions from both RO_x-RO_x and RO_x-NO_x reactions (Fig. 5b). Formation of peroxides comprises most of the former group, with equal contributions from HO₂+HO₂ and RO₂+HO₂ in simulation M0. The addition of reactive VOC in M1 doubles the rate of HO₂+HO₂ and triples the rate of RO₂+HO₂. PN formation comprises 65 %–86 % of RO_x-NO_x termination, with larger contributions at higher VOC and higher initial HONO. Pernitric acid formation (HO₂+NO₂) is 18 % of RO_x-NO_x termination in simulation S2c, reflecting fast formation in the concentrated plume followed by rapid dilution that outpaces thermal decomposition. Contributions of nitric acid (OH+NO₂) and nitroaromatic (AromNO₂) formation are 3 %–15 % and 0.1 %–6 % of RO_x-NO_x termination, respectively. The OH+X group includes reaction of OH with HONO and PNs to form NO₂ and other products. These reactions remove RO_x, but they are not strictly radical termination.

The balance of RO_x loss via NO_x and RO_x sinks, typically represented as the ratio of NO_x-related loss (L_N) to total radical loss or production (Q), quantifies the sensitivity of ozone production to VOC and NO_x availability (Kleinman et al., 1997; Kleinman, 2005). Here we define L_N as the sum of losses via formation of ANs, PNs, nitroaromatics, nitric acid, and pernitric acid (blue-shaded reactions in Fig. 5b). Traditionally, the assumption that HNO₃ formation is the dominant NO_x sink implies a transition from VOC to NO_x-sensitive O₃ production at $L_N/Q = 0.5$ (Kleinman et al., 1997). Non-negligible organic nitrate formation alters this threshold (Robinson et al., 2021; Schroeder et al., 2017).

We adopt a threshold of $L_N/Q = 0.41$ based on a recent study of western USA wildfires (Robinson et al., 2021).

Ozone production in the young plume is sensitive to both VOC and NO_x (Fig. 5c). All plotted simulations start with a ratio around 0.8 (VOC sensitive) and transition to NO_x sensitive within the first hour. This rapid shift is consistent with afternoon aging in other western USA wildfires (Robinson et al., 2021) and reflects sequestration of NO_x within PNs and other organic nitrates. The addition of VOC in simulation M1 accelerates this transition (more RO_x), while HONO slows the transition in M2c and M3b. Simulation M4b exhibits the fastest transition, where the NO₂ conversion to HONO amplifies RO_x and mitigates PAN formation.

The consequences of secondary chemistry assumptions become more apparent at later ages. Most simulations decay to steady L_N/Q values of 0.03–0.06 after 5 h of aging. Simulation M3b is the exception, maintaining L_N/Q around 0.2 due to a sustained NO_x source via pNO_3^- photolysis. The accuracy of this simulation is dubious due to a lack of HONO observations; however, the contrast between M3b and M4b illustrates the divergent effects of HONO production mechanisms on radical chemistry. Such differences can affect sensitivity to downwind perturbations, such as when mixing with urban (high NO_x) or biogenic (high VOC) air.

4.3 Implications for modeling biomass burning chemistry

Box model deficiencies temper the above results and underscore the challenges of simulating smoke plume chemistry. Simulations including both unmeasured reactive VOC and initial HONO or pNO_3^- photolysis (M2c or M3b) reasonably match observed NEMRs in the first 2 h of aging (Fig. 2); however, none of the scenarios explored here simultaneously reconcile O₃, NO_x, and PAN throughout the whole sample period. Errors due to assumptions about emissions and air mass history may become more significant further downwind; for example, the model does not capture the large decline in total observed NO_y (Fig. S17). Better observations of emission and background variability would reduce uncertainty, although this can be logistically challenging for large smoke plumes like the Rim Fire.

Errors in kinetics or VOC speciation may also contribute to model uncertainties. For example, our mechanism includes updated reaction rate coefficients for PA+HO₂ (faster by a factor of 1.33) and PAA+OH (slower by a factor of 123), based on recent laboratory results (Berasategui et al., 2020; Jenkin et al., 2019). Using MCM default values instead reduces model PAA NEMRs by half (results not shown). Analogous changes to other aspects of the mechanism, due to yet-unrecognized systematic errors, could influence other species. Over-prediction of PAN in simulations M2c and M3b may reflect errors in the thermal equilibrium, the NO/NO₂ ratio (under-predicted at later ages in simulation M3b), and/or VOC speciation. Regarding the last is-

Figure 5. Rates of RO_x initiation (a) and termination (b) integrated over the first five data points (Lagrangian age 0–2.3 h) via trapezoidal integration. In panel (a), oVOC + hv includes all oVOC photolysis reactions other than HCHO, and “other” includes NO₃ + VOC and other minor reactions. In panel (b), yellow–red and blue shades represent RO_x–RO_x and RO_x–NO_x reactions, respectively. AromNO₂ represents the formation of nitroaromatics, and PNs are the net formation of peroxy nitrates. OH + X (purple) represents reactions of OH with organic compounds (typically PNs), which result in formation of NO₂ and other non-RO_x products. The fraction of RO_x radicals lost via reactions with NO_x is shown in panel (c). Model simulations are as described in Fig. 2 and Table 1. The dashed line denotes the approximate transition between NO_x-sensitive and VOC-sensitive ozone production for biomass burning chemistry, as suggested by Robinson et al. (2021).

sue, acetaldehyde oxidation comprises half of PA production in our simulations, while the other half stems from mostly unmeasured precursors like methyl glyoxal (24 % of production; Fig. S25). Observations of major PAN precursors are necessary to close the PAN budget. Observations of PNs with specific precursors also afford complementary information; for example, over-prediction of acryloyl peroxyxynitrate (APAN) in most scenarios (Fig. S14) may imply that initial acrolein is too high. Observations of HONO, HO₂NO₂, and total NO_y would also help to fully constrain radical sources, cycling, and fate.

For regional and global models, whether and how to account for the full VOC distribution remains an open challenge. Advances in instrumentation have facilitated the quantification of myriad reactive gases (Heald and Kroll, 2020). Cumulatively, individually minor species can comprise a significant fraction of OH reactivity (Fig. 4) and potential organic aerosol mass (Gilman et al., 2015). Condensed mechanisms cannot represent this level of speciation. One option to reduce this complexity, similar to our methodology, is to identify proxy or surrogate species within a given mechanism based on mass, molecular formula, reactivity, volatility, or other metrics. Given the complexity of smoke plume chemistry, machine learning techniques may also prove use-

ful for condensing VOC into a manageable framework (Kelp et al., 2020). Multifaceted observations of emissions, oxidation products, and reaction intermediates can constrain representation of key chemical processes that influence the spatial and temporal extent of air quality and climate impacts.

Many atmospheric chemistry models do not incorporate primary emissions or the heterogeneous production of HONO in standard simulations. Primary HONO is a key oxidant source in young fire plumes (Peng et al., 2020). The HONO photolysis lifetime of 10–20 min can be of the order of, or much shorter than, an advection timescale for a single grid cell (e.g., a 12 km grid cell at a wind speed of 10 m s⁻¹ has an advection timescale of 20 min). Thus, instantaneous dilution may be a major hurdle to simulating this fast chemistry. Plume heterogeneity (e.g., a darker core) also confounds efforts to simulate chemistry in an average sense (Wang et al., 2021; Palm et al., 2021; Decker et al., 2021b). Putative secondary HONO sources are manifold (Zhang et al., 2019), as are associated uncertainties. A recent lab study of pNO₃⁻ photolysis on inorganic aerosol suggests a 10 times slower photolysis rate than assumed in simulation M3b (Shi et al., 2021), and a similar reduction was derived from an analysis of NO_y partitioning in polluted marine air (Romer et al., 2018). Other lab work has shown that the rate and product

yield of this reaction is sensitive to aerosol surface composition (Ma et al., 2021). Robust parameterizations will require continued systematic study of controlling factors, preferably under environmentally relevant and near-ambient conditions.

Wildfire emissions may have a more sustained influence on regional background chemistry than is currently appreciated. Synergistic increases in OH reactivity and oxidants in our sensitivity simulations stimulate production of multi-generation oVOC and organic NO_x reservoirs like PAN, which may alter the spatiotemporal scale of ozone and organic aerosol production. The modest decline of normalized excess OH reactivity (Fig. 4b) further implies that active chemistry persists far downwind. For example, the 62 % decrease in normalized excess OH reactivity in simulation M3b implies an effective pseudo-first-order photochemical lifetime of 12.2 h for the total OH sink. This aligns with a recent analysis of satellite observations suggesting an effective lifetime of 20 h or more for formaldehyde and glyoxal in aging smoke plumes (Alvarado et al., 2020). Space-based remote sensing of atmospheric composition may aid evaluation of model biomass burning emissions and chemistry on these scales.

5 Conclusions

Using a 0-D puff model constrained with SEAC⁴RS in situ observations, we have examined the gas-phase chemical evolution of the 2013 California Rim Fire plume and illustrated the sensitivity of chemistry to unmeasured reactive VOC and HONO. The rich measurement suite permits a holistic evaluation of the various components of the chemical system, including VOC, HO_x, NO_y, and O₃. Initializing with observed gases only, the model reasonably reproduces the evolution of O₃ over 12 h of aging but fails in other key aspects, including over-prediction of reactive VOC decay rates and under-prediction of NO_x and HCHO. Accounting for additional VOC identified by recent laboratory studies increases OH reactivity more than twofold throughout the simulation, drawing down model OH and generally degrading performance. Subsequent addition of HONO amplifies radical production and cycling. The addition of initial HONO (assumed to be primary emissions) or secondary production via *p*NO₃⁻ photolysis improves predictions of ozone, oVOC, and NO_x, while HONO production via NO₂ heterogeneous conversion generally degrades model performance. Further optimization simulations demonstrate that multiple combinations of enhanced VOC and primary/secondary HONO can minimize model–measurement bias with respect to O₃ and NO_x, although we cannot reconcile the model with all observations simultaneously. A decline in total observed NO_y with age may be due to unmeasured NO_y, changing NO_x emission ratios, or unmeasured background variability; the exact cause for this behavior remains unresolved. An examination of model reaction rates over the first 2.3 h of aging

demonstrates the potentially dominant contribution of oVOC photolysis to radical initiation, the importance of PN formation as a NO_x sink and the competitive roles of RO_x–RO_x and RO_x–NO_x reactions in radical termination. Ozone production is sensitive to both VOC and NO_x in the young plume for all sensitivity simulations. Ozone production transitions from VOC sensitive to NO_x sensitive after ~ 1 h of aging. The timing of this transition depends on VOC and HONO. Downwind NO_x sensitivity depends on the nature and efficacy of assumed secondary HONO / NO_x sources.

A primary finding of this study is that reactive VOC and oxidant sources are complementary in the wildfire-influenced atmosphere, and consideration of both is necessary for accurate simulation of near- and far-field impacts on atmospheric composition and air quality. Future efforts must focus on an efficient solution for incorporating this somewhat novel chemistry in regional and global models or else quantify the uncertainty associated with neglecting it.

This work also demonstrates the value of a near-comprehensive payload afforded by a heavy-lift aircraft like the NASA DC-8. The breadth of information in the SEAC⁴RS dataset enables a holistic examination of individual aspects of the chemical system within the context of the whole. Ongoing analysis of data from missions focused on biomass burning will illuminate the factors driving variability in reactive VOC, HONO, and other key aspects of fire plume chemistry. This same approach is beneficial for investigation of other complex environments (urban, biogenic, etc.) that comprise the lower troposphere.

Appendix A: Photolysis parameterization

For each puff, photolysis frequency J at solar time t (and a corresponding Lagrangian plume age) is calculated as follows:

$$J(t, \text{age}) = s J_{\text{cs}}(t) / r(\text{age}). \quad (\text{A1})$$

Here, $J_{\text{cs}}(t)$ is the clear-sky photolysis frequency and s and $r(\text{age})$ are observation-based scaling factors. Clear-sky photolysis frequencies stem from F0AM's hybrid parameterization, which combines solar spectra from the tropospheric ultraviolet and visible radiative transfer model (TUVv5.2, available at <https://www2.acom.ucar.edu/modeling/tropospheric-ultraviolet-and-visible-tuv-radiation-model>, last access: 22 February 2022) with the literature-recommended cross sections and quantum yields. This calculation uses actual SZA and measurement altitude. We assume an overhead ozone column of 290 DU and a surface albedo of 0.01. The age-dependent scaling factor $r(\text{age})$ is determined by fitting the ratio of clear sky to observed photolysis frequencies as a function of Lagrangian age, using a modified exponential as follows:

$$r(\text{age}) = r_0 e^{-\text{age}/\tau} + r_\infty (1 - e^{-\text{age}/\tau}). \quad (\text{A2})$$

Figure A1. (a) Average observed photolysis frequencies for each WAS sample for $O_3 \rightarrow O(^1D) + O_2$ (blue circles) and $NO_2 \rightarrow NO + O(^3P)$ (red diamonds). (b) Ratio of clear-sky to observed photolysis frequencies. Clear-sky values are calculated using tropospheric ultraviolet and visible radiative transfer model (TUV) solar spectra and FOAM parameterizations. Lines represent least squares fits to Eq. (A2). The two points between ages of 1–2 h are excluded from the fit.

Here, r_0 , r_∞ , and τ are fitting coefficients that vary for each J . Figure A1 illustrates this fit for ozone and NO_2 photolysis frequencies, which are suppressed by factors of 3.2 and 1.9, respectively, in the fresh plume. Fits capture 83%–92% of the variability in the clear-sky to observed ratio for all J values, with the exception of two points with ages of 1–2 h. These points are not included in the fit as they appear to be outliers, especially for $J(O^1D)$, and their inclusion would significantly degrade the overall fit quality. It is unclear why these points differ from the overall trend, as no other dilution or chemical markers show exceptional behavior at these times. The age correction is the same for all puffs. The other parameter, s , is a scalar multiplicative factor that adjusts model J values to agree with observations at trajectory endpoints (analogous to the scaling applied for trajectory meteorology) and is different for each puff.
